In auricular fibrillation the impulse instead of being initiated in the normal pacemaker the sinoauricular node, starts in a ring of muscle surrounding the superior vena cava, the inferior vena cava or both venae cavae The impulse continues to circulate in one of these rings of muscle in a manner similar to that of auricular flutter with the difference that the rate is much higher, ranging from 450 to 700 per minute averaging a rate of 550 per minute These waves are propagated to the auricular muscle but instead of traveling in a regular pathway as in auricular flutter encounter islands of refractory tissue so that their pathway varies from beat to beat This results in a variation in the cycle length and in the shape of the auricular complexes In auricular fibrillation there is no concerted contraction of the auricles as in flutter the auricles are in a continuous state of diastole and the auricular muscle is pervaded by numerous fibrillary twitchings This so called circus movement theory of Sir Thomas Lewis was challenged many years ago by German workers and has recently been challenged again by workers in this country The final answer is yet to be given

In the average untreated case of auricular fibrillation the ventricular rate ranges from 110 to 150 per minute Occasionally the rate may rise to 160 to 200 per minute Such high rates in older patients with arteriosclerotic heart disease may precipitate an attack of heart failure frequently accompanied by the picture of shock At times one may encounter auricular fibrillation where the ventricular rate without digitalis therapy ranges from 40 to 60 per minute Such instances are usually observed in older patients who have coronary arteriosclerosis and sclerotic changes in the A V node

*Etiology*.—Auricular fibrillation is almost always observed in the presence of myocardial disease, frequently of an advanced grade. It is rarely observed in normal hearts. The arrhythmia is observed in 60 per cent of the patients with heart failure. The most frequent associated factor is hypertensive arteriosclerotic cardiovascular disease, the next most frequent is rheumatic heart disease. These two conditions account for about 90 per cent of the cases of auricular fibrillation. Other associated factors are thyrotoxicosis and toxic states. It is also frequently seen in interauricular septal defects. It is rarely observed in syphilitic heart disease. Auricular fibrillation is rare below the age of 15; it is more common in men than in women, but the preponderance of males is chiefly in the non-rheumatic group, while in the rheumatic group the incidence is about equal.

*Symptoms and Signs*.—Patients with auricular fibrillation almost invariably demonstrate evidence of myocardial abnormality, often of a severe grade. They usually manifest evidence of heart dysfunction, namely, breathlessness, fatigue on slight exertion, precordial oppression, cyanosis, cardiac enlargement, rales at the lung bases, pleural effusion, edema of the legs and ascites, though there are those who go on for many years with no symptoms at all.

Auscultation reveals a characteristic type of irregular irregularity. This is most pronounced clinically at rates ranging from 90 to 130 per minute. When the ventricular rate is slow or very rapid the typical irregularity is difficult to determine clinically.

At fairly rapid rates during a short cardiac cycle the ventricular contraction often fails to lift the aortic valve. As a result only one heart sound is heard and the ventricular contraction is too weak to produce a pulse at the wrist. When many of these contractions occur it leads to a marked variation between the apical and pulse rates and this difference is known as a pulse deficit.

The heart sounds vary considerably in intensity, the louder sounds are heard following the longer pauses which permit greater ventricular filling. Cardiac murmurs undergo significant changes with the onset of auricular fibrillation. Systolic murmurs vary considerably in intensity depending on the length of the preceding cycle and consequent variation in ventricular filling; they are louder following the longer cycles and fainter after the shorter cycles. With rapid rates the murmurs become inaudible. The presystolic murmur of mitral stenosis due to failure of the auricles to contract is re-

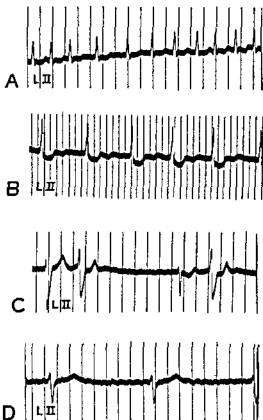

FIG. 145.—*Auricular Fibrillation Showing Varying Degrees of A-V Heart Block.* (A) Auricular fibrillation with rapid ventricular rate which averages 160 per minute. (B) After digitalization the ventricular rate is dropped to about 70 per minute. The ST segments are depressed. (C) Early toxic effects as indicated by slow ventricular rate with coupled extrasystoles (ventricular or nodal). (D) Auricular fibrillation with almost complete A-V heart block. Ventricular rate is about 32 per minute.

placed by a diastolic rumble with the onset of auricular fibrillation. Its intensity and the phase of diastole when it is heard vary with the cycle length.

*Pathology*.—The pathology of auricular fibrillation is that of the associated disease as mentioned above. In long standing cases

particularly those of rheumatic etiology, mural thrombi form in the auricular appendages and in the pectinate muscles. These are dislodged frequently, resulting in emboli to the brain, lungs, abdominal viscera and the lower extremities.

*Diagnosis*.—The diagnosis of auricular fibrillation may be suspected clinically in a patient manifesting an irregular type of irregularity. The characteristic symptoms and signs have been discussed above. Clinically, auricular fibrillation must be differentiated from multiple extrasystoles arising from different foci and auricular flutter associated with varying degrees of heart block. In the first two conditions exercise tends to make the rhythm quite regular, whereas in auricular fibrillation the rhythm becomes more irregular. The electrocardiogram usually establishes the diagnosis without doubt.

*Treatment*.—Since auricular fibrillation is usually associated with varying degrees of heart failure, therapy should be directed to this state in addition to the treatment of the irregularity. Digitalis is the drug of choice in the treatment of auricular fibrillation. It is in this condition that the greatest hopes for digitalis have been realized. Digitalis acts by impeding the passage of impulses from auricle to ventricle and thus slowing the rate. This is accomplished in two ways: by direct muscular effect and by a vagal effect on the A-V node. The maximum therapeutic effect is said to be reached when the apical rate drops to about 70 per minute with an elimination of the pulsus deficit. Digitalization may be performed rapidly in patients with a severe grade of heart failure and rapid rates or slowly in those where failure is slight or moderate in degree.

The approximate dose required for a 150 pound person is about 1.3 Gm. of the powdered leaf. This dose may be given over a period of 4 to 5 days when slow digitalization is adequate or within 1 to 2 days when rapid digitalization is necessary. When the patient presents a picture of severe congestive failure necessitating rapid digitalization and positive absorption, the parenteral route is indicated. Strophanthin 0.6 mgm. may be given intravenously, followed in 2 to 3 hours by 0.3 mgm. This last dose may be repeated if necessary in about 6 hours. Digalen, 2 to 3 cat units, may be administered intramuscularly and repeated 1 or 2 times in 6 to 8 hours, depending on the effect of previous doses on the heart. The digitalis glycosides may also be used in the doses as given for the treatment of heart failure. However, no matter what digitalis product is used, the patient's reaction will be the guide to dosage. Digitalis is contraindicated in patients with a slow ventricular rate, that is, below 50 per minute (independent of treatment) and this drug should not be given where the ventricular rate following therapy has decreased to 40 or 50 beats per minute. In such cases further slowing of the ventricular rate does harm by increasing the diastolic volume, which leads to stretching of the already diseased cardiac fibers. The dosage of digitalis necessary to produce this therapeutic effect varies considerably depending on the age of the patient and the underlying pathologic state, particularly the sclerotic changes in the A-V node in the older age group. Mercurial diuretics may also be used to overcome cardiac failure if this is present.

In the presence of thyrotoxicosis, toxic states and increased sympathetic tone, the dosage required to maintain a ventricular rate of from 70 to 80 per minute is usually higher than the average dose. On the other hand in older patients with sclerotic changes in the A-V node and those with overactive vagal tone, smaller doses usually suffice to slow the ventricular rate. Patients with aortic stenosis particularly are often sensitive to digitalis and usually can tolerate small doses only. It should be emphasized that an apical rate of 60 to 70 does not necessarily coincide with the maximum degree of improvement as far as congestive signs are concerned. Frequently edema may be present even at these slow rates. In such instances digitalis should not be further pushed. Instead the congestive signs should be treated by diuretics and other procedures such as low sodium diets.

Toxic effects of digitalis manifest themselves by the appearance of numerous ventricular extrasystoles, coupled rhythm, and sequences of two or more ventricular beat

With continuance of the drug ventricular paroxysmal tachycardia results. This is a dangerous type of arrhythmia since it predisposes the patient to ventricular fibrillation which is practically incompatible with life. It should be emphasized that these toxic effects may occur in the absence of nausea, vomiting, and other frequently mentioned toxic manifestations. These ectopic rhythms may be avoided by careful supervision of the digitalis dosage and by carefully following the patients both clinically and electrocardiographically. When such toxic effects appear, digitalis should be stopped immediately. Should they continue to the stage of ventricular tachycardia, quinidine sulfate may be administered in an endeavor to abolish this arrhythmia. Recently procaine amide (250 mg. to 1 gm. every 4 hours) has been found to be equally, if not more effective than quinidine for the treatment of ventricular tachycardia.

The continuance of auricular fibrillation involves three problems: the circulatory dynamics are relatively inefficient as compared to what is present with normal rhythm, continuous digitalization is necessary, and most important there is a constant danger of embolic phenomena leading to serious complications depending on the organ involved.

Quinidine sulfate may be administered to patients with auricular fibrillation where it is desired to convert the irregularity to a normal sinus rhythm. It is indicated where the onset of fibrillation is relatively recent, where the heart is not severely diseased and where the auricles, as observed fluoroscopically, are not greatly enlarged. In such cases quinidine is efficient in converting the fibrillation to normal rhythm in over 50 per cent of patients. Frequently quinidine administration must be maintained for two to three months after normal rhythm has been restored since cessation may lead to the return of auricular fibrillation. Quinidine sulfate is also indicated in the prevention of attacks of paroxysmal auricular fibrillation. The dose of quinidine varies from 0.366 Gm. to 0.6 Gm. every 2 hours for 10 doses unless the attack of fibrillation is terminated earlier.

One of the dangers to be considered in the restoration of normal rhythm is the possibility of emboli being thrown off into the circulation. Statistics relative to this occurrence vary considerably because it is difficult to differentiate embolic phenomena which occur as a result of the restoration of normal rhythm from those which occur as a result of the underlying cardiac state. In those cases where the fibrillation is of less than three months' duration the danger of embolic phenomena is slight as compared to the benefits to be derived. This danger of embolization can now be markedly reduced by anticoagulant therapy. The patient is given enough anticoagulant to bring the prothrombin time to about three times normal, then the quinidine is given while anticoagulant therapy is maintained. This has apparently reduced the danger of embolization.

Auricular fibrillation which results from thyrotoxicosis usually disappears following successful thyroid surgery with restoration of basal metabolism to normal. Quinidine may be of help to those patients in whom the restoration of normal rhythm is somewhat delayed.

Auricular fibrillation which results from rheumatic activity, some toxic process or disturbance of metabolism tends to return to normal rhythm with the cessation of these processes unless the damage to the auricular muscle has been severe with resultant irreversible changes.

*Prognosis.*—The prognosis in auricular fibrillation depends on the age of the patient, the underlying cardiac condition, the presence of cardiac enlargement, the presence of heart failure, and the ease with which the apical rate and heart failure are controlled. In addition complicating factors such as renal or cerebral disease or the presence of embolic phenomena may modify the prognosis.

## Paroxysmal Auricular Tachycardia

In paroxysmal auricular tachycardia the cardiac impulse, instead of originating in the normal pacemaker, the sinoauricular node, starts from a focus situated anywhere in the auricles outside the normal site of origin. The paroxysms usually start suddenly, last a few seconds, hours or days, and usually

end suddenly The known limits of the auricular rate range from 140 to 220 per minute Patients subject to these paroxysms often present a history of isolated auricular extrasystoles which gradually become more numerous, occur more frequently, and later appear as a sequence of two or more beats If six auricular extrasystoles are observed occurring in succession they may be said to constitute a short paroxysm of auricular tachycardia Because of their ectopic origin, the P waves during the paroxysm vary in configuration to a greater or lesser degree from those observed during the normal mechanism As in auricular extrasystoles they may be flattened, upright or inverted With rapid rates, the P waves blend with or may be submerged in the T waves The P-R intervals are slightly but not significantly shortened by the tachycardia

The QRS complexes in auricular tachycardia usually possess the normal configuration Associated with rapid ventricular rates, however the ventricular complexes may be widened, probably the result of fatigue of one of the bundle branches

Two types of auricular paroxysmal tachycardia may be observed In the common type the ventricles respond to every beat of the auricles, in the less common type the auricular tachycardia is associated with varying degrees of A-V heart block so that with an auricular rate which ranges from 150 to 200 per minute the ventricular rate is 75 or 100 per minute

Patients subject to attacks of paroxysmal auricular tachycardia sometimes present electrocardiograms which during the period of normal rhythm show a short P R interval with a widened QRS complex (Wolff-Parkinson-White syndrome ) Aside from the tendency of these patients to develop this arrhythmia their hearts are usually normal clinically

*Etiology* —The underlying etiology in paroxysmal auricular tachycardia is not known Since this disturbance is observed in a considerable number of hearts (about 50 per cent) which are considered to be clinically normal various theories for its production have been advanced Among them are disturbances of the physiochemical mechanism in the auricles, allergic states and high degrees of sympathetic tone In the remaining 50 per cent this condition is observed in the presence of damage to the auricular muscle in patients with rheumatic, hypertensive and arteriosclerotic heart disease, and in toxic states The type of auricular tachycardia associated with A-V heart block is observed usually in the older age groups in association (1) with toxic digitalis effects and (2) in the presence of coronary arteriosclerosis

*Symptoms and Signs* —The symptoms of auricular paroxysmal tachycardia are similar to those observed in the presence of any ectopic rhythm and depend largely on the state of the heart muscle and its response to an acceleration of the heart beat, the duration of the paroxysm and the nervous make-up of the patient These may vary from a relative freedom from symptoms except for slight palpitation to varying degrees of precordial discomfort and a feeling of marked anxiety associated with considerable precordial pain

The signs of auricular paroxysmal tachycardia are those of an accelerated heart action superimposed on the types of hearts mentioned above Gallop rhythm and pulsus alternans are encountered not infrequently during the paroxysm Heart failure and the anginal syndrome may also be observed Occasionally especially in the older age group with arteriosclerosis, the paroxysm may precipitate the picture of shock resembling that of an acute myocardial infarction While deaths occurring during paroxysmal auricular tachycardia are rare they have been observed

*Pathology* —The pathology of auricular paroxysmal tachycardia is that of the underlying states mentioned above No specific pathology has been described

*Diagnosis* —The diagnosis of auricular paroxysmal tachycardia should be suspected in a patient who gives a history of a sudden acceleration of the heart beat which lasts for varying periods of time and stops suddenly The presence in the past of auricular extrasystoles is suggestive evidence The presence of a regular rhythm during the paroxysm the rate of which ranges from 140 to 220 per minute should lead one to suspect

auricular paroxysmal tachycardia as the cause. The differential diagnosis involves simple tachycardia, auricular flutter, and ventricular tachycardia. Of these three abnormal mechanisms, paroxysmal auricular tachycardia is the only one which, when responding to carotid sinus pressure, results in a sudden restoration of the normal mechanism, the latter being maintained for relatively long periods of time. Ventricular tachycardia is uninfluenced by carotid sinus pressure and in auricular flutter a slowing of ventricular rate, if obtained, is maintained only during the period of carotid sinus stimulation. Some patients with a sinus tachycardia and a sensitive carotid sinus mechanism may also develop a slowing of the rate during pressure with a rapid return to the original rate on relief of the pressure. The final diagnosis is usually clearly established by the electrocardiogram.

*Treatment.*—The treatment of simple paroxysmal tachycardia may be divided into (a) treatment during attacks and (b) treatment between attacks.

(a) During the attack, the following procedures may be tried: application of carotid sinus pressure. In order to properly apply this pressure the patient should be placed in the recumbent or semi-recumbent position. The carotid artery should be palpated as high up in the neck as possible and pressed firmly against the vertebral column. This vessel is frequently an elusive structure and one must make certain that the carotid artery and not soft tissue of the neck is pressed upon as described above. During the maintenence of pressure a stethoscope should be continually applied to the precordium and as soon as the heart stops the pressing finger should be immediately removed. Simultaneous bilateral carotid sinus pressure should never be applied. We have never seen any accidents result from this procedure when applied as directed above though permanent and transient hemiplegias have been reported in a few cases. Ocular pressure is not advised routinely because of untoward effects which have been observed. The patient himself as a result of experience frequently employs similar procedures such as pressure applied to various parts of the neck, particularly in the region of the carotid sinus, bending down, stretching the neck as far back as possible, holding the breath, yawning, or inserting the hand in the throat to induce vomiting. These procedures have vagal stimulation as their basis.

The following drugs may be given during the paroxysm if carotid sinus pressure fails to restore normal rhythm.

(1) Digitalis intramuscularly, 2 to 3 cat units repeated in one to two hours if necessary. The intravenous route has also been recommended but we rarely find this necessary. Carotid sinus pressure, if previously ineffective, frequently slows the heart beat after digitalis administration.

(2) Magnesium sulfate—10 cc. of a 20% solution administered intravenously.

(3) Calcium gluconate—10 cc. of a 10% solution intravenously. If efficacious the paroxysm will stop immediately.

(4) Quinidine sulfate—0.3 Gm. intramuscularly hourly for 5 to 6 doses or for longer periods. Quinine dihydrochloride—0.3 Gm. diluted in 20 to 50 cc. of normal saline may be given slowly intravenously or the same dose diluted to 5 or 10 cc. may be given subcutaneously. Quinidine may be given by mouth in a dose of 0.2 to 0.3 Gm. every hour for ten or more doses.

(5) Mecholyl—25 to 50 mg. subcutaneously. This often results in cessation of the paroxysm, however this drug usually produces a profound fall in the systemic blood pressure. Periods of ventricular fibrillation after its administration have been observed. It should be used cautiously in the very young, the very old, and in asthmatic individuals. When the drug is given one should always have a syringe of 1.2 mgm. of atropine ready to counteract untoward effects.

(6) Ipecac—may be given by mouth in the form of the syrup in a dose of 4 to 15 cc. to induce vomiting.

(7) Prostigmine—1 to 2 cc. of 1:2000 solution is given intramuscularly. While it may not be effective in itself it increases the sensitivity of the carotid sinus about 20 minutes after its administration so that it frequently renders the previously insensitive carotid sinus sensitive to carotid sinus stimulation.

(8) Fugarin—though toxic in some cases may stop attacks.

(9) Neosynephrine—given intravenously in 0.5 to 2.0 mgm. doses may restore normal rhythm in less than a minute. This action is attributable to reflex cardiac inhibition elicited by the rapid rise in pressure in the carotid sinuses and aortic arch.

(10) Other sympatheolytic drugs such as tetraethyl ammonium chloride are effective in stopping paroxysms, but their use is not desirable because of their generalized effect.

(11) Pronestyl (procaine amide) in doses of 250 mgm. to 1 Gm. every 4 hours has recently been found to be effective in some cases.

(b) The treatment between attacks involves ascertaining the precipitating cause of the attacks if possible and treating it. Nervous states, abdominal distension, excessive exertion and allergic factors may all be provocative causes. If the paroxysms occur frequently, the following procedures are usually helpful: quinidine sulfate—0.2 Gm, four to five times per day; digitalization followed by a maintenance dose which may be continued for months. Prostigmine bromide 15 mgm. 4 times daily orally has also been advised. Occasional cases are encountered where these procedures do not suffice and paroxysms continue. Then thoracic sympathectomy has been suggested as a remedy. This procedure by reducing sympathetic cardiac effects has been successful in stopping paroxysms in a certain number of cases.

*Prognosis.*—The prognosis of paroxysmal auricular tachycardia is usually good in so far as individual attacks are concerned except (a) in a long continued paroxysm, (b) when severe myocardial damage is present, (c) and in those infrequent instances where the attacks recur repeatedly in spite of therapy.

## Auriculoventricular Heart Block

A-V heart block may be divided into two types, partial and complete. The first stage of A-V heart block is said to occur when the A-V conduction time (P-R interval) exceeds 0.20 second. As the degree of block increases the A-V conduction time becomes longer and longer until dropped beats occur, that is, the ventricles fail to respond to some auricular beats. This particular type of partial block is known as the Wenckebach phenomenon. In a still higher grade of block there may be observed 2 to 1, 3 to 1, 4 to 1 or a still higher degree of partial A-V heart block. As the block further increases a stage is reached when the ventricles fail to respond to any auricular impulses, with the result that these two chambers beat entirely independent of each other. When this stage is reached *the degree of A-V heart block is said to be complete.*

In complete A-V heart block the auricles beat regularly at a rate of 70 to 80 per minute in response to their pacemaker, the sinoauricular node, and the ventricles also beat regularly at a rate of 20 to 40 per minute in response to their center located either in the lower portion of the A-V node or the upper portion of the interventricular septum. In complete A-V heart block the auricles and ventricles beat entirely independently of each other. The auricular rate is influenced by the vagus and its rate can be speeded by emotion, exercise or atropine. These factors do not affect the ventricular rate since it is no longer controlled by the vagus. The ventricular rate in complete heart block may rarely be affected by marked changes in the sympathetic tone such as that produced following the injection of adrenalin or in fever. The ventricular rate in complete A-V heart block rarely exceeds 40 per minute. Under certain conditions the ventricular rate may reach 70 to 100 per minute; this may occur following toxic digitalis effects and in anoxic states, for example, immediately after emergence from a Stokes-Adams seizure.

*Etiology.*—A-V heart block may occur at any age. Partial A-V heart block in individuals below the age of 35 is due usually either to digitalis effects or to rheumatic involvement in the acute, subacute or healed stage. In acute rheumatic fever prolongation of the A-V conduction time is usually observed as an extremely transient phenomenon. However, it is occasionally observed in a healed stage many years after the acute rheumatic infection has subsided.

Minor grades of A-V heart block may be observed in many conditions, for example

congenital heart disease rheumatoid arthritis subacute bacterial endocarditis and other infections Recently doubt has been cast upon the specificity of a prolongation of the P R interval in the diagnosis of rheumatic fever in the younger age group This is due to the increasing frequency with which prolongation of the A V conduction time has been observed in other infections for example mumps poliomyelitis etc Rarely is it observed in syphilis and occasionally it is seen in the absence of demonstrable heart disease The position of the patient has recently been shown to affect the P R interval In some subjects prolongation has been noted in the recumbent position when it was absent with the patient sitting upright

*Pathology* —In partial A-V heart block the pathology depends on the underlying disease If the result of rheumatic fever one may observe Aschoff bodies in various stages of healing cellular infiltration and isolated areas of fibrosis Other infections also produce inflammatory and toxic changes which may impair conduction through this tissue In sclerotic processes the A V node is partially or almost entirely replaced by fibrous tissue with only islands of muscle tissue remaining Occasionally the A-V node is severed by a calcareous plaque In another type of complete A V block the lesion is observed as a fibrotic scar severing both bundle branches as they emerge from the bundle of His Gummata occurring in the A V node or the bundle of His are rare

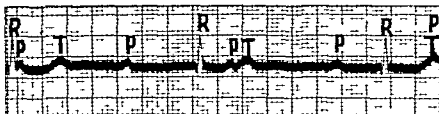

Fig 146 —Complete auriculo-ventricular block Lead I

Above the age of 35 rheumatic heart disease is a less important factor digitalis and other conditions are to be considered as causative In the later decades coronary artery disease and sclerotic processes involving the A-V node are chiefly responsible Syphilis is rarely a factor In complete A V heart block the preponderating causes are coronary arteriosclerosis and sclerotic processes involving the A V node Rare causes are congenital heart disease gumma and acute coronary occlusion involving the right coronary artery at the point where it turns sharply to become the posterior descending branch of the right coronary artery

Recently attention has been focused on a group of patients who develop A V heart block of varying grades due to vagal stimulation caused by reflexes originating in the gastrointestinal tract and other portions of the body and following local constriction about the neck in the region of the carotid sinus

In some cases no organic pathologic cause for the block can be found

*Symptoms and Signs* —In partial A V heart block no symptoms may be observed due to the block itself even with a slow ventricular rate The symptoms are those of the underlying disease Some cases of complete A V heart block present no symptoms Others complain of fatigue on exertion consciousness of the heart slowly beating and occasional precordial pain These patients usually cannot engage in strenuous physical exertion but usually do fairly well on a reduced physical regimen

As a result of the slow rate alterations in the cardiovascular dynamics appear The cardiac output per beat is increased but the cardiac output per minute is decreased The systolic blood pressure rises to about 170 to 200 per minute and left ventricular hypertrophy results These patients are subject to Stokes Adams attacks which are discussed below

(9) Neosynephrine—given intravenously in 0.5 to 2.5 mgm. doses, may restore normal rhythm in less than a minute. This action is attributable to reflex cardiac inhibition elicited by the rapid rise in pressure in the carotid sinuses and aortic arch.

(10) Other sympatheolytic drugs such as tetraethyl ammonium chloride are effective in stopping paroxysms, but their use is not desirable because of their generalized effect.

(11) Pronestyl (procaine amide) in doses of 250 mgm. to 1 Gm. every 4 hours has recently been found to be effective in some cases.

(b) The treatment between attacks involves ascertaining the precipitating cause of the attacks if possible and treating it. Nervous states, abdominal distension, excessive exertion and allergic factors may all be provocative causes. If the paroxysms occur frequently, the following procedures are usually helpful: quinidine sulfate—0.2 Gm. four to five times per day; digitalization followed by a maintenance dose which may be continued for months. Prostigmine bromide 15 mgm. 4 times daily orally has also been advised. Occasional cases are encountered where these procedures do not suffice and paroxysms continue. Then thoracic sympathectomy has been suggested as a remedy. This procedure by reducing sympathetic cardiac effects has been successful in stopping paroxysms in a certain number of cases.

*Prognosis.*—The prognosis of paroxysmal auricular tachycardia is usually good in so far as individual attacks are concerned except (a) in a long-continued paroxysm, (b) when severe myocardial damage is present, (c) and in those infrequent instances where the attacks recur repeatedly in spite of therapy.

## Auriculoventricular Heart Block

A-V heart block may be divided into two types: partial and complete. The first stage of A-V heart block is said to occur when the A-V conduction time (P-R interval) exceeds 0.20 second. As the degree of block increases the A-V conduction time becomes longer and longer until dropped beats occur, that is, the ventricles fail to respond to some auricular beats. This particular type of partial block is known as the Wenckebach phenomenon. In a still higher grade of block there may be observed 2 to 1, 3 to 1, 4 to 1 or a still higher degree of partial A-V heart block. As the block further increases a stage is reached when the ventricles fail to respond to any auricular impulses, with the result that these two chambers beat entirely independent of each other. When this stage is reached the degree of A-V heart block is said to be complete.

In complete A-V heart block the auricles beat regularly at a rate of 70 to 80 per minute in response to their pacemaker, the sinoauricular node, and the ventricles also beat regularly at a rate of 20 to 40 per minute in response to their center located either in the lower portion of the A-V node or the upper portion of the interventricular septum. In complete A-V heart block the auricles and ventricles beat entirely independently of each other. The auricular rate is influenced by the vagus and its rate can be speeded by emotion, exercise or atropine. These factors do not affect the ventricular rate since it is no longer controlled by the vagus. The ventricular rate in complete heart block may rarely be affected by marked changes in the sympathetic tone such as that produced following the injection of adrenalin or in fever. The ventricular rate in complete A-V heart block rarely exceeds 40 per minute. Under certain conditions the ventricular rate may reach 70 to 100 per minute; this may occur following toxic digitalis effects and in anoxic states, for example, immediately after emergence from a Stokes-Adams seizure.

*Etiology.*—A-V heart block may occur at any age. Partial A-V heart block in individuals below the age of 35 is due usually either to digitalis effects or to rheumatic involvement in the acute, subacute or healed stage. In acute rheumatic fever prolongation of the A-V conduction time is usually observed as an extremely transient phenomenon. However, it is occasionally observed in a healed stage many years after the acute rheumatic infection has subsided.

Minor grades of A-V heart block may be observed in many conditions, for example

Procaine amide may be tried when the above drugs fail

*Prognosis* —The prognosis of partial A-V heart block depends on the underlying etiology and can best be determined by evaluation of the heart as a whole The heart block in itself does not kill Most of these patients die from heart failure or the underlying disease Occasionally cases are observed which change from partial to complete A V heart block and back again

Complete A V heart block is much more serious although instances where such patients have lived 10 to 20 years have been recorded The patient except in rare instances *must live a sedentary existence* especially if subject to Stokes-Adams attacks No therapy for the block itself is required if the patient is free of seizures

muscle In some instances this is clearly the result of disease of the heart muscle resulting from various etiologies inflammatory degenerative or toxic states anoxia and poisons especially digitalis In many instances the exact cause is not revealed even after careful clinical examination and investigation Two theories have been advanced for the production of extrasystoles (1) that of re-entry suggests that the normal beat stimulates a portion of the heart muscle to produce the ectopic beat (2) that of parasystole which suggests that in addition to the normal pacemaker another center is active in the heart muscle producing extrasystolic beats independently at all times but breaking through the regular rhythm only occasionally

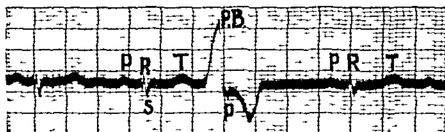

Fig 147 —Ventricular premature beat with retrograde stimulation of the auricles Lead III

## Extrasystoles or Premature Contractions

The normal rhythm consists of a regular sequence of beats arising in the sinoauricular node transmitted to the auricles and then through the A V node to the ventricles Each impulse is part of a rhythmic series The extrasystoles arise prematurely thus disturbing the rhythmic series of beats and may be followed by a compensatory pause Extrasystoles may arise in the auricles, the ventricles or the A V nodal tissue Premature contractions arising in the ventricles *are always followed* by a compensatory pause (except in the rare type of interpolated extrasystoles) in auricular and nodal premature beats the following cycle is usually less than that of a compensatory pause The exact cause or mode of production of extrasystoles *is not known* They apparently arise from an irritable focus in the heart

*Etiology* —The etiology underlying extrasystoles is not well known Often they occur in hearts that are clinically normal Premature beats have been recorded at all ages They are rare in the first decade their incidence is greatest in the age groups between 50 and 70 years Such beats may be observed singly or in groups of two or three The following conditions are known to produce extrasystoles infectious diseases especially rheumatic fever scarlet fever and diphtheria toxic digitalis effects severe grades of myocardial disease for example coronary occlusion and anoxic states foci of infection overactivity of the sympathetic system may exaggerate the tendency to produce extrasystoles especially if they are already present certain psychoneurotic states reflexes from gastrointestinal disturbances tobacco and coffee are probably overrated as causes posture is often a factor usually they are more frequent in the re

*Diagnosis*.—With prolongation of the conduction time (prolonged P-R interval) there results a diminished intensity of the first heart sound which may be marked. If the P-R interval is sufficiently prolonged it may produce a gallop sound (summation gallop). This gallop sound is heard best at rates over 100 per minute and is the result of auricular contraction superimposed upon the wave of early diastolic ventricular filling. With a higher grade of partial block, dropped beats may be detected. These pauses may be abolished by exercise; they are at times difficult to differentiate from the compensatory pause following an extrasystole. Occasionally the auricular sounds may be audible in the higher grades of A-V heart block.

When the heart beats regularly between 30 to 50 per minute, an A-V heart block may be suspected. In partial block exercise or amyl nitrite abruptly doubles the ventricular rate. When the apical rate is regular and ranges from 20 to 40 per minute and is unaffected by exercise or atropine, complete A-V heart block should be suspected. The first heart sound varies in intensity because of the varying A-V intervals. When the auricular and ventricular contractions occur close together the first sound is relatively loud; when they are far apart the first sound is faint.

The important symptoms to be considered in the higher grades of partial and complete block are the development of giddiness, fainting, and temporary loss of consciousness (Stokes-Adams syndrome). These seizures occur during the transition from partial to complete heart block as well as during the course of complete A-V heart block. They result from periods of asystole which last from 3 to 9 seconds or longer and consist of syncopal attacks or actual convulsive seizures. The following are the underlying mechanisms recorded electrocardiographically during the seizures: (a) a prefibrillary type of ventricular tachycardia, (b) ventricular fibrillation, (c) standstill of the whole heart, (d) ventricular standstill with maintenance of auricular beating. These mechanisms may occur either singly or in combination. Recognition of these various types is important in therapy. Death frequently occurs during a Stokes Adams seizure; indeed, this is the most frequent cause of death in complete A-V heart block. The patient may experience many seizures before death finally supervenes, sometimes over a period of 3 to 5 years.

*Treatment*.—No treatment is required for minor grades of A-V heart block. The treatment is that of the underlying cause if ascertained, for example, rheumatic heart disease or other infection. Although digitalis may be given to patients with A-V heart block, one should be somewhat more cautious on its administration because of the greater susceptibility to higher grades of A-V heart block. Established complete heart block, however, is preferable to shifting degrees of block.

The higher grades of A-V heart block are usually chronic and fixed. The routine of the patient should be governed by his general fitness. All those who experience syncopal attacks should be warned of the danger of getting about on their own, because of their susceptibility to syncopal seizures. We have seen such patients who have been treated for years for epilepsy.

The treatment of attacks of Stokes Adams syndrome depends on the underlying mechanism which unfortunately cannot be determined clinically during the attacks, so graphic means must be used. The following measures may be used during the attacks: direct vigorous thumping on the precordium (more likely to be of help in ventricular standstill); intracardiac or intramyocardial injection of adrenalin (for the same type). The occurrence of frequent seizures one following the other, is usually the result of a severe degree of cerebral anoxia, and nearly always indicates a terminal event. We have seen this state improve by oxygen and the intravenous injection of aminophylline. To prevent the Stokes Adams seizures sympathetic stimulants such as ephedrine sulfate 25 mgm., t.i.d., or other sympathicommetic drugs may be given. Thyroid extract and barium chloride have been used. Where these attacks are associated with the prefibrillary type of ventricular tachycardia or ventricular fibrillation quinidine may be given prophylactically. Large doses of papaverine have also been recommended both prophylactically and during attacks.

control of the sinoauricular node. When this is the case some other name (ventricular escape or nodal escape) is given to the disturbance. The A-V node readily takes up the role of pacemaker if either of the following developments takes place: (1) The rhythmicity of the sinoauricular node becomes depressed to a level lower than that inherent in the auriculoventricular node or (2) the rhythmicity inherent in the auriculoventricular node becomes heightened to a point above that of the sinoauricular node. Since the natural rhythmicity of the auriculoventricular node is around 40 to 50 per minute the former development (1) results in a slow heart rate and may be called the slow type of nodal rhythm while the latter (2) produces a rate more rapid than the usual sinus rate and can be referred to as the rapid type of nodal rhythm. Neither type is very common but the slow form is seen more often than the rapid. Both forms of A-V nodal rhythm are nearly always temporary disturbances; only a few instances have been reported where the disturbance approached permanency.

*Etiology.*—A-V nodal rhythm is rare in children. It is observed most frequently in the middle and later decades of life. Among the causes of nodal rhythm are those factors which tend to temporarily inhibit the function of the sinoauricular node or to permanently damage the structure. Vagal stimulation, certain phases of respiration and the initial stage of atropine effect may produce transient periods of nodal rhythm. Injury to the sinoauricular node by toxic processes, myocarditis, especially rheumatic carditis, and degenerative states may result in relatively long periods of nodal rhythm. Digitalis and certain toxic states occasionally produce nodal rhythm when the auriculoventricular rate may be 60 or more per minute.

*Pathology.*—The pathology is that of the conditions described above. The sinus node may be the seat of extensive damage or entirely destroyed by the disease process.

*Symptoms and Signs.*—No symptoms are produced by A-V rhythm itself. The symptoms are those of the underlying cardiac state. Shortness of breath, consciousness of the heart beating slowly, the slow heart rate or irregular heart action are the chief complaints. No signs are observed except a persistent slow pulse which is entirely regular. The rate undergoes slight variations and occasionally marked variations, particularly following exercise or emotion, at which time the auricles and the ventricles beat at a slightly different rate. This also gives rise to variation in the intensity of the first heart sound due to the mechanism described under complete A-V heart block. Not infrequently the premature nodal contractions are associated with and add to the irregularity.

*Diagnosis.*—Although A-V nodal rhythm may be suspected when the apical rate is regular and ranges from 40 to 50 per minute the diagnosis is confirmed chiefly by means of the electrocardiogram. In considering the electrocardiographic diagnosis of A-V nodal rhythm it should be pointed out that the A-V node is a relatively long structure, so much so that the electrocardiographic findings differ depending upon whether the impulses arise in the head or auricular end, in the tail or ventricular end, or in the center. What is seen usually is a migration of the center of impulse formation with some impulses arising from one situation in the node and some from another. Regardless of which center is active there is one common feature: the auricular P waves are inverted or at least different in shape from P waves originating in the sinus node. This is so because an impulse arising in the A-V node follows an entirely different course through the auricular muscle than one arising in the sinus node. The QRS complexes are usually supraventricular, that is, normal in width and shape, though occasionally one sees a slight aberration in the shape of this complex.

When an impulse arises in the ventricular end of the node it has a much shorter distance to go to reach the ventricles than the auricles. Consequently the ventricles are activated and contract before the auricles with the result that inverted P waves are usually situated between the QRS complex and the T wave.

When an impulse arises in the auricular end of the node the distance to be traversed to the auricles is short and the auricles beat

cumbent position Extrasystoles are observed more frequently at slow rates, they are less often observed at high rates Although extrasystoles are usually abolished by exercise there is a small group where they are induced by or are rendered more numerous by exercise This phenomenon is usually observed in hearts which show evidence of myocardial abnormality Extrasystoles that are numerous and arise from different foci are observed in the presence of myocardial damage

*Symptoms* — There may be no symptoms as a result of extrasystoles Frequently however the patient is conscious of what he calls palpitation the heart turns over or the heart stops While in itself this may be of little or no importance the thought that there is something wrong with the heart renders the patient panicky and he feels the imminence of a serious catastrophe Occurring frequently these symptoms arouse intense anxiety on the part of the patient The history frequently given is that they are more troublesome while resting particularly while lying in bed

*Diagnosis* — The interruption of a normal rhythm by premature beats followed by a pause which usually but not invariably is compensatory is a characteristic finding on auscultation These pauses are often difficult to differentiate from those that appear during the Wenckebach phenomenon of partial A-V heart block or the pauses of marked sinus arrhythmia When the period between the extrasystole and the preceding normal beat is short ventricular filling is small and the extrasystolic beat may not be sufficiently strong to open the aortic valve and will therefore fail to produce a palpable pulse at the wrist In these cycles only one sound is heard over the heart The presence of a normal beat followed by an extrasystole repeated in regular sequence is characteristic of coupled rhythm Clinically coupling may be mistaken for alternation of the pulse because of the alternation of weak and strong beats Coupled rhythm is characterized by a rhythmic irregularity consisting of a short pause between the normal beat and the extrasystole and the long compensatory pause following the extrasystole In pulsus alternans the rhythm is quite regular When extrasystoles occur frequently and arise from many different foci the rhythm is indistinguishable clinically from that of auricular fibrillation Most extrasystoles disappear following exercise in occasional cases they become more frequent after exercise This last group is the more serious variety and is the result of myocardial damage The diagnosis of extrasystoles and their exact origin may be determined by the electrocardiogram

*Treatment* — The treatment of extrasystoles is frequently rather unsatisfactory Therapy should be directed to the underlying cause if it can be determined If it is myocardial disease improvement of the heart by rest diuretics, and digitalis may abolish the extrasystoles Gastrointestinal disturbances foci of infection and exogenous poisons should be sought for and removed if possible Frequently the cause cannot be found and in the symptomatic variety the patient should be reassured that they are a normal phenomenon and that they occur frequently in normal hearts If they are frequent and are troublesome to the patient the following therapy is suggested quinidine sulfate 0 2 Gm four or five times daily papaverin 0 06 to 0 2 Gm t i d , potassium acetate, 2 to 4 Gm in a 25 per cent solution of peppermint water every 4 to 6 hours bromides 1 Gm t i d phenobarbital 0 03 Gm t i d Recently procaine amide in doses of 0 25 to 0 5 Gm every 4 to 6 hours has been used in the treatment of ventricular and at times in auricular extrasystoles Psychotherapy is indicated in those cases where emotional conflict may be a factor in the production of the extrasystoles

*Prognosis* — The prognosis depends upon the underlying condition of the myocardium the incidence and grouping of the ectopic beats and the response to therapy

### Auriculoventricular Nodal Rhythm

The term A V nodal rhythm is usually applied when the impulses arising in the A V node either slowly or rapidly spread downward to the ventricles and upward to the auricles and thus control both chambers This is not always the case however for frequently nodal impulses go only to the ventricles while the auricles remain under

control of the sinoauricular node When this is the case some other name (ventricular escape or nodal escape) is given to the disturbance The A V node readily takes up the role of pacemaker if either of the following developments takes place (1) The rhythmicity of the sinoauricular node becomes depressed to a level lower than that inherent in the auriculoventricular node or (2) the rhythmicity inherent in the auriculoventricular node becomes heightened to a point above that of the sinoauricular node Since the natural rhythmicity of the auriculoventricular node is around 40 to 50 per minute the former development (1) results in a slow heart rate and may be called the slow type of nodal rhythm while the latter (2) produces a rate more rapid than the usual sinus rate and can be referred to as the rapid type of nodal rhythm Neither type is very common but the slow form is seen more often than the rapid Both forms of A V nodal rhythm are nearly always temporary disturbances only a few instances have been reported where the disturbance approached permanency

*Etiology* —A V nodal rhythm is rare in children It is observed most frequently in the middle and later decades of life Among the causes of nodal rhythm are those factors which tend to temporarily inhibit the function of the sinoauricular node or to permanently damage the structure Vagal stimulation certain phases of respiration and the initial stage of atropine effect may produce transient periods of nodal rhythm Injury to the sinoauricular node by toxic processes myocarditis especially rheumatic carditis and degenerative states may result in relatively long periods of nodal rhythm Digitalis and certain toxic states occasionally produce nodal rhythm when the auriculoventricular rate may be 60 or more per minute

*Pathology* —The pathology is that of the conditions described above The sinus node may be the seat of extensive damage or entirely destroyed by the disease process

*Symptoms and Signs* —No symptoms are produced by A V rhythm itself The symptoms are those of the underlying cardiac state Shortness of breath consciousness of the heart beating slowly the slow heart rate or irregular heart action are the chief complaints No signs are observed except a persistent slow pulse which is entirely regular The rate undergoes slight variations and occasionally marked variations particularly following exercise or emotion at which time the auricles and the ventricles beat at a slightly different rate This also gives rise to variation in the intensity of the first heart sound due to the mechanism described under complete A V heart block Not infrequently the premature nodal contractions are associated with and add to the irregularity

*Diagnosis* —Although A V nodal rhythm may be suspected when the apical rate is regular and ranges from 40 to 50 per minute the diagnosis is confirmed chiefly by means of the electrocardiogram In considering the electrocardiographic diagnosis of A V nodal rhythm it should be pointed out that the A V node is a relatively long structure so so much so that the electrocardiographic findings differ depending upon whether the impulses arise in the head or auricular end in the tail or ventricular end or in the center What is seen usually is a migration of the center of impulse formation with some impulses arising from one situation in the node and some from another Regardless of which center is active there is one common feature the auricular P waves are inverted or at least different in shape from P waves originating in the sinus node This is so because an impulse arising in the A-V node follows an entirely different course through the auricular muscle than one arising in the sinus node The QRS complexes are usually supraventricular that is normal in width and shape though occasionally one sees a slight aberration in the shape of this complex

When an impulse arises in the ventricular end of the node it has a much shorter distance to go to reach the ventricles than the auricles Consequently the ventricles are activated and contract before the auricles with the result that inverted P waves are usually situated between the QRS complex and the T wave

When an impulse arises in the auricular end of the node the distance to be traversed to the auricles is short and the auricles beat

before the ventricles However, as the impulse is spreading from its point of origin upwards (towards the auricles) it is also spreading towards the ventricle with the result that when the impulse reaches the auricles and the P wave begins to be written, the impulse will be well on its way by then through the node toward the ventricles This naturally results in the P R intervals being quite short

When the impulse arises around the center of the node, it may reach the auricles and ventricles simultaneously, with the result that the QRS complexes and the P waves occur simultaneously and the latter are invisible When this is the case, the diagnosis is *sometimes uncertain and must be arrived* at largely through elimination If one takes enough tracings, usually a cycle or cycles will be found in which the P wave slows, for as we have already stated, the center of impulse formation in the A-V node generally moves and rarely remains fixed However if this does not occur, the following procedures may help

(1) Exercise or atropine may be given to separate the auricular and ventricular rhythms these act by decreasing vagal tone which often affects the sinoauricular node to a greater degree than the A V node

(2) A record of the jugular pulse simultaneously with the electrocardiogram will record an *A* wave occurring synchronously *with the QRS complex*

*A V Nodal Extrasystoles and Nodal Paroxysmal Tachycardia* —A nodal extrasystole is simply a single cycle of rapid type nodal rhythm That is for one cycle the rhythmicity of the A V node is raised to a higher level than that of the sinoauricular node The electrocardiographic features are as previously described inverted P waves either before *behind or buried in the QRS* complexes If before the QRS complexes the P R interval will be shortened If instead of a single isolated nodal extrasystole there occurs a series of these beats this constitutes nodal paroxysmal tachycardia As the name implies it is paroxysmal and the rate may rise as high as 140 to 160 per minute This disturbance is the typical example of the rapid type of nodal *rhythm* but it is quite rare

*Ventricular Escape* —This term applies to those instances in which impulses arising in the A V node go forward and control the ventricle but do not reach the *auricles*, which remain under the control of the sinoauricular node The factors which produce this disturbance and the form in which it manifests itself (slow or rapid) are those already discussed

The "slow" type is easily recognized in the electrocardiogram by the fact that the escaped ventricular complexes are not preceded by P waves The latter can usually be seen at least partially, behind the QRS complexes and can be seen to be normally upright and therefore of sinus origin In the "rapid" type, we have an A-V *dissoci*ation with the ventricles beating more rapidly than the auricles This can be plainly seen in the electrocardiogram by the fact that the ventricular beats are of normal shape but are not preceded by P waves with a constant P-R interval The ventricular complexes are regular in rhythm and are all responses to nodal impulses, except that an occasional beat may be out of rhythm because it is a response to an auricular and not a nodal impulse This can happen when the auricular impulse finds the refractory state of the A-V node and the *ventricles* favorable The P waves are normally upright regular and occur at a slower rate than the ventricular complexes

*Treatment* —If there is an underlying cause such as digitalis it should be removed Any toxic or disease state present should be treated If the condition results from vagal effect, atropine or ephedrine, in doses large enough to produce physiologic effects must be used

*Prognosis* —This depends upon the underlying factors producing the nodal rhythm

## Paroxysmal Ventricular Tachycardia

Paroxysmal ventricular tachycardia is a rather rare but serious type of arrhythmia When a series of six or more ventricular extrasystoles occur in succession they may be said to constitute a paroxysm of ventricular *tachycardia* Its evolution may be observed in serial tracings Occasional ven

tricular extrasystoles initially present are observed to become more numerous and later either coupled rhythm appears or they are observed to occur in sequences of two or three beats. Following this short and then longer paroxysms of ventricular tachycardia may appear. A paroxysm may last a few hours, days or weeks. The danger of this disturbance lies not only in its association with a severely damaged heart and the tendency to exhaustion of the heart muscle but also the predisposal of such rhythm to develop into ventricular fibrillation, a condition practically incompatible with life.

The following types of ventricular tachycardia are observed:

(1) Runs of ventricular extrasystoles all of which have the same configuration with a rate ranging from 130 to 180 per minute.

(2) A bidirectional type of ventricular tachycardia which is usually the result of toxic digitalis effects and which has been regarded by some as a "circus movement" in the ventricles and has been called ventricular flutter. This type is almost always fatal.

(3) A prefibrillary type of ventricular tachycardia which is characterized by extremely bizarre ventricular complexes, the rate of which ranges from 200 to 250 per minute. Such complexes are observed usually immediately preceding or upon emergence from attacks of Stokes-Adams seizures.

*Etiology.*—Paroxysmal ventricular tachycardia almost always occurs in the presence of severe myocardial damage. It is rarely observed in patients where hearts are apparently normal clinically. The following are the most important associations: toxic digitalis effects, myocardial infarction, severe grade of hypertensive and arteriosclerotic heart disease.

*Symptoms and Signs.*—The symptoms of ventricular tachycardia are similar to those of any ectopic rhythm but are apt to be more severe since they are observed in severely damaged hearts.

*Pathology.*—No distinct pathology is observed except that of the underlying conditions mentioned above.

*Diagnosis.*—The diagnosis of paroxysmal ventricular tachycardia is difficult to establish clinically; it can be definitely made by the electrocardiogram. It should be suspected in any instance where the ventricular rate varies from 130 to 180 per minute which does not yield to carotid sinus pressure and there is slight irregularity of the ventricular rate and variation of intensity of the heart sounds because of the superposition of auricular and ventricular contractions at various cycles. The factors in establishing the diagnosis are: the beats of the paroxysms must be ectopic in origin and must conform to those observed as isolated extrasystoles before the onset of the paroxysm; the first beat of the paroxysm must bear the same relation to the preceding normal beat as a coupled extrasystole bears to the preceding normal beat; the ventricles are observed beating regularly at a rate of 130 to 180 per minute and the auricles also beat regularly, slower than and entirely independently of the ventricles. Occasionally ventricular tachycardia is observed in the presence of auricular fibrillation.

The differential diagnosis from the electrocardiographic standpoint involves any ectopic rhythm where the QRS complexes are widened as a result of fatigue of one of the bundle branches incident to the rapid rate. Such widening of the QRS complexes may be observed in auricular tachycardia, auricular flutter and nodal tachycardia.

*Treatment.*—Quinidine is the drug of choice in the treatment of ventricular tachycardia. This may be given by mouth, intramuscularly or intravenously. The dose given by mouth or intramuscularly ranges from 0.2 to 0.3 Gm. four to five times per day. Sometimes larger doses up to 0.6 Gm. per hour are given for 10 or 20 doses. The intramuscular route is used when the patient is in some degree of shock and absorption by mouth may be slow and uncertain. Occasionally quinidine dihydrochloride 0.3 Gm. diluted in 20 to 50 cc. of normal saline is effective when given intravenously. Quinidine acts in stopping a paroxysm of ventricular tachycardia by increasing the refractory period of the ventricle. Other drugs which have been used are potassium chloride 2 Gm. every 2 to 4 hours to supplement or reinforce action of the quinidine; atropine sulfate 2.0 mgm. hypodermically; magnesium sulfate 15 cc. of a 20 per cent

solution, papaverine, 0 2 to 0 3 Gm every 3 hours The treatment by quinidine is effective in about one-half to two thirds of the cases The mistake often made is that the patient is not given enough of this drug

Recently, procaine has been given intravenously to stop paroxysms of ventricular tachycardia with some success Procaine amide has also been used orally in doses of 0 25 to 0 5 gm every 4 to 6 hours or intravenously in doses of from 200 to 1000 mgm Procaine amide is considered by some the drug of choice in the control of ventricular tachycardia The oral dose is 250 mg to 0 5 Gm every 4 hours The intravenous dose is 0 2 to 1 Gm given during a period of 5 to 10 min

*Prognosis* —The prognosis of paroxysmal ventricular tachycardia is extremely serious because it occurs in severely damaged hearts and its duration for a prolonged period predisposes to ventricular fibrillation, a condition which is incompatible with life

### Ventricular Fibrillation

Ventricular fibrillation is the most serious of the arrhythmias its presence is practically incompatible with life Indeed it is often present as a terminal event in dying hearts Comparatively few cases in the human have been recorded by the electrocardiogram These have been obtained when by chance the machine was connected to the patient usually during repeated Stokes Adams attacks In ventricular fibrillation numerous fibrillary impulses traverse the ventricle so rapidly that coordinated contractions do not occur The ventricles are in a continuous state of dilatation similar to that of the auricles in auricular fibrillation The blood pressure drops to zero and unless the mechanism spontaneously changes in a matter of seconds death ensues Electrocardiographic records have been obtained where the patient observed in these seizures spontaneously recovered and the heart returned to a normal ventricular contraction Such instances are rare Patients having developed this mechanism once are subject to repeated attacks so that death is usually not long delayed The etiologic factors associated with this condition have not been established clearly in the human because of the relatively few opportunities to study this condition by reason of its transient nature Many studies have been made in the experimental laboratories with animals and it is believed that the results can largely be applied to man Ventricular fibrillation has been produced by electric shock ligation of the branches of the coronary arteries, by digitalis poisoning and by adrenalin Similar analogous conditions are probably also operative in the production of ventricular fibrillation in the human The myocardial states associated with ventricular tachycardia are probably also a factor in the production of ventricular fibrillation

The diagnosis of ventricular fibrillation cannot be made clinically It is presumed to be present in patients dying from coronary occlusion and digitalis toxicity Its presence is strongly suspected during Stokes-Adams seizures this is particularly so if during the attack the pulse rate previously 20 to 40 per minute jumps to 100 or over per minute (This is usually due to the prefibrillary type of ventricular tachycardia which usually precedes ventricular fibrillation ) In patients subject to attacks quinidine sulfate or procaine amide may be given as a prophylactic measure Administration of epinephrine during a seizure is contraindicated since in itself it may produce ventricular fibrillation and thus may prevent spontaneous recovery Large doses of papaverine have also been recommended for use between and during attacks of ventricular fibrillation Procaine and diethylaminoethanol may also stop a bout of this arrhythmia In occasional cases, electric shock applied to the exposed heart has been effective in restoring a normal rhythm

### Treatment of Rapid Ectopic Rhythms When Exact Diagnosis by Electrocardiogram is Not Available

Not infrequently one encounters patients with rapid heart rates which are the result of an ectopic rhythm These patients are often in a severe state of heart failure and in the absence of an electrocardiogram the

question often arises as to the proper treatment The following summarizes the principles of therapy in those cases

1 Over 90 per cent of ectopic rhythms with rates ranging from 140 to 180 per minute are due to rapid auricular fibrillation auricular tachycardia and auricular flutter

2 These arrhythmias usually respond to digitalis action and its administration may be lifesaving

3 Digitalis is of no value in ventricular tachycardia *it is of course contraindicated* when this tachycardia is the result of toxic digitalis effects

## COR PULMONALE

Cor pulmonale is right sided heart enlargement due to disease in the pulmonary bed right heart failure and tricuspid lesions or congenital defects It is either acute or chronic

### Acute Cor Pulmonale

*Etiology* —Acute cor pulmonale is caused by sudden obstruction of the pulmonary artery or one of its branches usually by a clot Such a clot originates (1) in a leg or pelvic vein (2) in the right side of the heart particularly the right auricle especially when a patient with auricular fibrillation suddenly develops a normal rhythm (3) in the rupture of an aortic aneurysm into the pulmonary artery and (4) in vegetation from an ulcerated pulmonary valve About 60 per cent of the cases of acute cor pulmonale are due to medical causes about 40 per cent to surgical causes Of the medical cases half are due to cardiac causes half to noncardiac causes Chronic heart failure with pulmonary congestion may also result in pulmonary infarcts the so-called autochthonous infarcts

*Pathologic Physiology* —With the lodging of an embolus in the pulmonary artery *there will be a dilatation of the artery distal* to the embolus and a dilatation of the right ventricle The thrombus may become more or less organized if the patient survives for some period of time The lung area involved *by the thrombus shows* hemorrhagic infarction usually surrounded by an area of pneumonitis This area of hemorrhagic infarction may develop infection and abscess formation The presence of the thrombus throws an increasing strain on the right ventricle so that it gradually dilates There will also be diminished aeration of the blood sent to the lung because there is less functioning pulmonary tissue A spasm of the coronary artery will also result this is due to the so-called pulmonocoronary reflex In addition to that all the other pulmonary vessels will suffer spasm this will throw still *greater strain* upon the right side of the heart

*Signs and Symptoms* —The symptoms of pulmonary embolism depend on the site of the involvement and the size of the vessel occluded In the typical surgical case the *embolus occurs from 10 to 14 days after* abdominal or pelvic surgery or after childbirth The victim is seized with a sudden agonizing pain or oppression in the substernal region accompanied by the symptoms of shock this either while he is lying quietly or just after he attempts to sit up Death may be instantaneous Pallor and profuse sweating accompanied by a low blood pressure and a rapid pulse may occur Cough and hemoptysis are usually but not invariably present If the embolus is small the symptoms may be slight In many cases of pulmonary embolism the above mentioned symptoms are absent or so mild as to pass unnoticed even when the embolus is of fair size At times, there may even be multiple small emboli with a minimum of signs or symptoms These cases will often simulate a mild pneumonitis *In addition to* dyspnea and cyanosis and a shock like picture the heart rate is rapid and the pulmonic second sound is accentuated One may also hear a systolic murmur over the pulmonic area *There will be increased pulsation in the* second and third interspace to the left of the sternum The blood pressure is low and during the first twenty four hours no pulmonary signs may be observed Thereafter *two types of pulmonary findings* may appear In one type there is evidence of congestion of a localized area of the lung usually the right base In the other type there is a wedge shaped triangular area of congestion In some cases though it is not common in addition to the above findings, one may note jaundice

*X-ray Findings.*—The x-ray signs do not ordinarily appear for from 24 to 36 hours. Usually they consist of an area of pneumonitis like congestion at the right base or (more rarely) a triangular area of consolidation. In doubtful cases, one may use angiocardiography to demonstrate the obstructed pulmonary-artery branch and so confirm the diagnosis.

*Electrocardiogram.*—The electrocardiogram is not pathognomonic in the diagnosis of pulmonary infarction, though it may be a help when serial tracings are taken. The findings depend upon the presence of right ventricular strain and anoxia. In the characteristic case one will find a deep S wave in lead I, a low to inverted T wave in lead II, a Q wave in lead III, and a deeply inverted T wave in lead III. Furthermore the RT segment in lead III may be elevated, the T wave in the precordial leads is flattened or inverted, the RT segment may be depressed and the QT interval may be prolonged. There may also be a delay in the onset of the intrinsicoid deflection in leads over the right precordium and the right ventricular pattern may be noted far over to the left in the precordial leads. Occasionally transient right bundle branch block may be observed.

*Differential Diagnosis.*—Acute cor pulmonale must principally be distinguished from coronary occlusion. A history of recent operation, findings of right ventricular strain, evidence of pulmonary infarction and absence of characteristic electrocardiographic evidence of coronary occlusion speak for pulmonary embolism. Acute cor pulmonale must also be differentiated from dissecting aneurysm of the aorta and spontaneous pneumothorax. The development of a spontaneous mediastinal emphysema may also be mistaken for acute cor pulmonale, but if the so called "crunch" sound over the heart in systole is present, the condition is not cor pulmonale.

*Treatment.*—Treatment against the development of pulmonary emboli is becoming more and more common. Early ambulation of surgical patients has reduced the incidence of phlebothrombosis of the leg, and medical patients who may be expected to develop emboli are now treated prophylactically with such agents as heparin, dicumarol and other anticoagulants. This is routine for patients who have had coronary occlusion or have auricular fibrillation and have already suffered one pulmonary embolus. Furthermore, before an attempt is made to restore an auricular fibrillation of some standing to a regular sinus rhythm, it is recommended that the patient be prophylactically treated with anticoagulants.

Once a pulmonary embolism has occurred the patient should be put to bed and given oxygen, as well as morphine and atropine. Papaverine in doses of from 0.06 to 0.12 Gm. should be given intravenously at 2 to 4 hour intervals in an attempt to overcome vascular spasm. In addition the patient should be heparinized at once and then given dicumarol to prevent further embolization. In some clinics, it is also the custom to ligate any peripheral veins which have been found to contain thrombus formation. But the value of this procedure is now seriously questioned.

Stellate block has also been used to treat the acute episode of pulmonary embolism. This procedure acts by preventing reflex vascular spasm, thereby reducing the strain on the right side of the heart.

## Chronic Cor Pulmonale

*Etiology.*—Chronic cor pulmonale is gradual in development and permits the right side of the heart to adjust itself to the enlargement.

Left heart failure is a common cause of chronic cor pulmonale, for as the left side of the heart fails, pulmonary congestion develops and throws an extra load upon the right ventricle and hypertrophy results. Mitral stenosis is also a common cause of chronic cor pulmonale, for back pressure from the left auricle into the lungs results in pulmonary congestion and right ventricular strain follows. Furthermore, in rheumatic heart disease, the common cause of mitral stenosis, the elasticity of the lung is reduced and pulmonary endarteritis develops. Both of these factors result in right ventricular strain because it elevates the pulmonary pressure by raising resistance to the flow of the blood through the lungs. This increased

resistance results from the widespread destruction of the interalveolar septa and the findings of one usually accompany evidences of the other

The *principal manifestations* of right sided heart failure are cyanosis polycythemia clubbing of the fingers engorgement of the superficial veins increased venous pressure swelling and tenderness of the liver (and occasionally of the spleen) edema of the legs transudations into the serous cavities, eventual dilatation of the right ventricle and right auricle and tricuspid insufficiency (as evidenced by a systolic murmur and accentuation of the second pulmonic sound) Occasionally a diastolic pulmonary murmur may be heard the result of a relative insufficiency of the pulmonary valve so-called right sided gallop rhythm may be heard at times Oliguria as well as a rise in cerebrospinal fluid pressure may be observed too The dyspnea present varies in intensity The circulation time is usually not altered in early cases of chronic cor pulmonale but is increased when heart failure occurs

*X ray Findings* —In long standing cases the x ray shows enlargement of the right auricle particularly with the onset of the right heart failure Enlargement of the pulmonary artery, with increased pulsation of that artery is a characteristic finding In the posteroanterior view of the heart one of the first signs of right sided heart enlargement may be a prominence of the pulmonary artery segment and in the right anterior oblique position enlargement of the right ventricle as well as of the pulmonary artery will be seen The lung fields will be clear in pure right sided heart failure though if left sided heart failure has preceded it there will be evidences of pulmonary congestion

*Electrocardiographic Findings* —The electrocardiogram usually shows a right axis deviation In the precordial leads there are evidences of right ventricular hypertrophy and these findings are borne out in the unipolar leads There may be broad notched P waves and right bundle branch block is a common finding There is delay in onset of the intrinsicoid deflection in right precordial leads and the right ventricular pattern may be seen in the 4 5 and even 6 positions over the precordium Auricular fibrillation is a common arrhythmia in chronic cor pulmonale

*Course* —The onset of chronic cor pulmonale is insidious Heart failure may not occur for many years Acute pulmonary infections superadded to lung disease already present may cause sudden death Congestive heart failure rarely causes death in patients with pure right sided heart failure unless pulmonary arteriosclerotic changes take place then death comes quickly once cyanosis has developed

*Treatment* —The treatment of this condition consists in correcting the underlying pulmonary disease or other conditions putting strain on the right side of the heart In most cases this is hard to do But the antibiotics and new procedures in pulmonary surgery have made it easier The treatment of right sided heart failure is like that for congestive failure

The use of oxygen however presents certain hazards Patients with chronic cor pulmonale have so high a carbon dioxide level in the blood that carbon dioxide fails to stimulate their respiration Their only stimulus to respiration then is the low oxygen tension If these patients are placed in an atmosphere of 100 per cent oxygen the stimulus to respiration may cease and the patient die It is therefore wise to use oxygen mixtures for these patients or keep them in 100 per cent oxygen only intermittently for periods of from 15 to 20 minutes till there is re-establishment of the carbon dioxide stimulus to respiration

Change of climate may also be helpful in these cases by helping prevent secondary pulmonary infection Such cases do best in temperate climates and low altitudes

## THE TREATMENT OF HEART FAILURE

There are several classifications of heart failure The discussion here is limited to some of the more important types *Low output failure* is seen in hypertension stenosis of the aortic and mitral valves coronary atherosclerosis and myocarditis either degenerative or inflammatory Here there is

*X-ray Findings.*—The *x*-ray signs do not ordinarily appear for from 24 to 36 hours. Usually, they consist of an area of pneumonitis like congestion at the right base or (more rarely) a triangular area of consolidation. In doubtful cases, one may use angiocardiography to demonstrate the obstructed pulmonary artery branch and so confirm the diagnosis.

*Electrocardiogram.*—The electrocardiogram is not pathognomonic in the diagnosis of pulmonary infarction, though it may be a help when serial tracings are taken. The findings depend upon the presence of right-ventricular strain and anoxia. In the characteristic case one will find a deep S wave in lead I, a low to inverted T wave in lead II, a Q wave in lead III, and a deeply inverted T wave in lead III. Furthermore the RT segment in lead III may be elevated, the T wave in the precordial leads is flattened or inverted, the RT segment may be depressed, and the QT interval may be prolonged. There may also be a delay in the onset of the intrinsicoid deflection in leads over the right precordium and the right ventricular pattern may be noted far over to the left in the precordial leads. Occasionally, transient right bundle branch block may be observed.

*Differential Diagnosis.*—Acute cor pulmonale must principally be distinguished from coronary occlusion. A history of recent operation, findings of right-ventricular strain, evidence of pulmonary infarction, and absence of characteristic electrocardiographic evidence of coronary occlusion speak for pulmonary embolism. Acute cor pulmonale must also be differentiated from dissecting aneurysm of the aorta and spontaneous pneumothorax. The development of a spontaneous mediastinal emphysema may also be mistaken for acute cor pulmonale, but if the so called crunch sound over the heart in systole is present, the condition is not cor pulmonale.

*Treatment.*—Treatment against the development of pulmonary emboli is becoming more and more common. Early ambulation of surgical patients has reduced the incidence of phlebothrombosis of the leg, and medical patients who may be expected to develop emboli are now treated prophylactically with such agents as heparin, dicumarol, and other anticoagulants. This is routine for patients who have had coronary occlusion or have auricular fibrillation and have already suffered one pulmonary embolus. Furthermore, before an attempt is made to restore an auricular fibrillation of some standing to a regular sinus rhythm, it is recommended that the patient be prophylactically treated with anticoagulants.

Once a pulmonary embolism has occurred the patient should be put to bed and given oxygen as well as morphine and atropine. Papaverine in doses of from 0.06 to 0.12 Gm. should be given intravenously at 2 to 4 hour intervals in an attempt to overcome vascular spasm. In addition, the patient should be heparinized at once and then given dicumarol to prevent further embolization. In some clinics it is also the custom to ligate any peripheral veins which have been found to contain thrombus formation. But the value of this procedure is now seriously questioned.

Stellate block has also been used to treat the acute episode of pulmonary embolism. This procedure acts by preventing reflex vascular spasm thereby reducing the strain on the right side of the heart.

## CHRONIC COR PULMONALE

*Etiology.*—Chronic cor pulmonale is gradual in development and permits the right side of the heart to adjust itself to the enlargement.

Left heart failure is a common cause of chronic cor pulmonale, for as the left side of the heart fails, pulmonary congestion develops and throws an extra load upon the right ventricle and hypertrophy results. Mitral stenosis is also a common cause of chronic cor pulmonale, for back pressure from the left auricle into the lungs results in pulmonary congestion and right ventricular strain follows. Furthermore, in rheumatic heart disease, the common cause of mitral stenosis, the elasticity of the lung is reduced and pulmonary endarteritis develops. Both of these factors result in right ventricular strain because it elevates the pulmonary pressure by raising resistance to the flow of the blood through the lungs. This increased

### TREATMENT OF EDEMA

*Diuretics* — The use of the mercurial diuretics is probably the most important single method employed in treating the edema of heart failure. These agents prevent the reabsorption of sodium by the renal tubule. Considerable amounts of sodium are therefore eliminated in the urine and large amounts of water are carried with this electrolyte. The diuretic may be given intravenously, subcutaneously, intramuscularly, orally or rectally.

Relatively few contraindications to the administration of the mercurial diuretics exist. They may be given even when albumin is present in the urine or a mild or moderate azotemia exists. The chief contraindications to their use are acute glomerulonephritis and marked azotemia of renal origin.

The patient should be weighed upon admission to the hospital, or when first seen by the physician, and daily during the administration of the diuretic. The frequency of administration of mercurial diuretics in the initial stages of congestive heart failure is as follows: initial dosage—0.5 to 1.0 cc subcutaneously or intramuscularly repeated daily or increased to 2.0 cc until a considerable amount of fluid is removed; subsequent dosage—1.0 to 2.0 cc every other day or every third day until most of the extracellular fluid has been removed (patient will fail to lose more weight after an injection of the diuretic—so called dry weight), then it should be given every one or two weeks or oftener as indicated by patient's weight, symptoms and signs. Mercurial diuretics sometimes have untoward effects. Sudden death has been reported following the administration of such diuretics. In older patients, especially in hot weather, the mercurial diuretics must be used with caution since in these patients such diuretics may cause weakness, apathy, leg cramps, a shock like state and even death. These episodes may be *observed* as the result of the loss of electrolytes, especially chloride and sodium and occasionally *calcium*. Such untoward effects may be prevented by the administration of smaller doses of the mercurials, the administration of salt before and after the administration of these diuretics, and observation of the level of serum sodium, especially in patients on a sodium poor diet. Calcium may prevent leg cramps in some patients and quinine in others.

Coronary occlusion has also followed the administration of the mercurials. Occasionally patients develop extrasystoles as a result of having been given mercurial diuretics. Fatal arrythmias have also occurred. It is believed that digitalization before administration of a mercurial diuretic results in extrasystoles because of a redigitalization due to the action of the glycoside in the reabsorbed extracellular fluid.

Occasional instances of renal shut down with intractable anuria have apparently resulted from the administration of mercurial diuretics, even though it has been proved that they will in themselves not produce kidney pathology.

Deficiencies of the water soluble vitamins may also result from the administration of these diuretics.

Patients who have received the mercurial diuretics with good response over a period of months or years sometimes reach a point at which they no longer respond to them. The treatment of such mercurial fast patients involves a rather serious problem. First one should differentiate such cases from cases of oliguria due to mechanical factors, such as the presence of ascites and/or a fall in blood pressure with decreased renal blood flow. By removing the mechanical factors, such as the ascitic fluid or by restoring the blood pressure to a more normal level, diuresis may again be established. If the patient becomes mercurial fast, the following must be considered: (1) inadequate digitalization (if the patient is not adequately digitalized, this may be a factor and should be corrected), (2) over digitalization (this too may be a factor in preventing proper utilization of the mercurial diuretics), (3) hypochloremic alkalosis (when the chloride level drops below 86 mEq the patient will become refractory to the mercurial diuretics and one must then give ammonium chloride orally or intravenously, though the latter method is somewhat dangerous), (4) hyponatremia (sodium

an increase in venous pressure, and the work of the heart is increased to a point at which the heart goes into failure and its output drops In *high-output failure,* the cardiac output is initially high and often associated with an increase in the circulating blood volume It is seen in severe anemias, emphysema, chronic cor pulmonale, thyrotoxicosis beriberi heart disease, arteriovenous aneurysms, pregnancy, osteitis deformans interauricular septal defect, and in neuroses associated with increased metabolic rates with increased demands on the heart Here in the presence of heart failure the cardiac output remains high

In *left-sided heart failure* the manifestations consist of pulmonary congestion and pleural effusion In *right-sided heart failure* there is evidence of congestion of the liver increased venous pressure, ascites, and edema of the lower extremities

*Methods of Treatment* —The treatment of heart failure may be discussed under the following (1) rest of the heart (2) cardiac edema (3) acute heart failure (4) surgery, (5) additional measures

### *Decrease of Cardiac Work*

*Bed Rest* —The importance of bed rest in the treatment of heart failure cannot be overemphasized Bed rest not only reduces the work of the heart to a minimum but decreases the metabolic demands of the tissues for blood Bed rest is not nearly so important, however in cases of left heart failure as in cases of right heart failure In left heart failure the periods of bed rest may sometimes be curtailed to about one or two days Then if the patient sits up fluid will gravitate to the lower portions of the body and diminish the strain on the heart In right heart failure bed rest may be prolonged to two or three weeks If bed rest is too prolonged especially if the patient is old, hypostatic congestion of the lungs followed by pneumonia, phlebothrombosis with pulmonary infarction or (though seldom) arterial thrombosis may develop furthermore decalcification of bone and urinary difficulties may also occur Patients over fifty or with a tendency to phlebothrombosis should be encouraged to exercise their arms and legs and move about in bed as much as possible, and they should be allowed to get up as soon as their condition permits The use of anticoagulants as a prophylactic measure against the development of vascular occlusion in such patients particularly in those with auricular fibrillation is gaining popularity rapidly

*Low Calorie Diet* —A diet containing from 800 to 1000 calories reduces the work of the heart by reducing the metabolic rate which may drop to minus 20 or minus 30 per cent Weight loss, especially in the obese patient, is also important, since bringing the weight down to the optimal range may not only improve the exercise powers of the heart but postpone for years the onset of heart failure obesity strains the heart by increasing metabolic demands and causing fatty changes in the heart which are deleterious to the optimum function of that organ

*Drugs for Lowering Metabolism* —The introduction of such drugs as propylthiouracil and methylthiouracil, drugs capable of reducing the basal metabolic rate, have also been used in attempts to lower the demands of the body upon the heart Propyl thiouracil in doses of 100 mg given every 8 hours has been used not only for patients with thyrotoxicosis but also for patients with heart failure unassociated with thyroid disease The exact status of this method of treatment is not yet certain

*Treatment of Rapid Rate* —The occurrence of an arrhythmia with a rapid ventricular rate results in myocardial exhaustion due to abbreviation of the diastolic rest period of the heart This condition may even produce heart failure in the normal heart A rapid ventricular rate associated with auricular flutter or auricular fibrillation responds to digitalis Paroxysmal auricular tachycardia may be abolished by carotid-sinus pressure by the administration of prostigmine plus carotid sinus pressure by digitalization or by the administration of quinidine Nodal tachycardia yields to similar therapeutic measures Ventricular tachycardia can usually be abolished with quinidine or pronestyl (*see* section on the treatment of arrhythmias)

help the heart and enable diuretics and digitalis to act more efficiently. Pericardial effusions resulting from congestive heart failure are usually not large enough to require paracentesis. But where pericardial effusions are great and heart failure results it is advisable to remove the effusion in order to increase cardiac efficiency. In the occasional patient with marked edema of the extremities Southey tubes may be used to help drain off the excess fluid.

### Digitalis in Heart Failure

*Preparation and Dosage.*—Many preparations of digitalis drugs and their glycosides are available for the treatment of heart failure. The type of preparation used depends on the individual preference and the mode of administration. The drug may be given orally, intravenously or intramuscularly, the first being the most popular. The following preparations are commonly used if the drug is given orally: the powdered leaf, digitoxin, digoxin, digilanid, lanatoside C and cedilanid. The following table lists the drugs, the amount commonly required for full digitalizing dose and recommended daily maintenance dose.

The initial digitalizing dose is that recommended for a patient weighing 150 pounds (about 70 kilos); however, the dose required for full digitalization varies considerably with the patient. Sometimes twice the recommended dose is required or even more. Although the recommended digitalizing dose is sometimes administered all at one time, it is best to give half the dose initially and the other half in two doses at twelve-hour intervals. Toxic effects rarely occur with the lower digitalizing dose mentioned. They not infrequently occur with higher doses.

| *Drug* | *Full Digitalization Dose by Vein* | *Full Digitalization Dose by Mouth* | *Daily Maintenance Dose* |
|---|---|---|---|
| Digitalis leaf | 3-5 cat units (Digalin) | 15 cat units (22 1/2 gr.) | 1/2 to 1 cat unit |
| Digilanid | 3.0 mg. | 15 cat units (3.0-8.0 mg.) | 0.3 mg. |
| Digitoxin | 1.25 mg. | 1.2 to 3.6 mg. | 0.05 to 0.2 mg. |
| Digoxin | 1.2 mg. | 2 to 5 mg. | 0.25 to 0.75 mg. |
| Gitalin | — | 6.5 mg. | 0.25 to 0.75 mg. |
| Cedilanid (Lanatoside C) | 1.6 mg. | 5 to 10 mg. | 0.5 to 1.2 mg. |
| Oubain | 0.7-1.0 mg. | — | — |
| Strophanthin | 0.7-1.0 mg. | — | — |
| Strophoside | 1.0 mg. | — | — |
| Scillaren | 1.0-1.75 mg. | 9-14 mg. | 0.8-1.6 mg. |

Summary of Effects and Doses of Digitoxin, Digoxin and Lanatoside C

| | *Digoxin* | *Digitoxin* | *Lanatoside C* |
|---|---|---|---|
| Daily undivided dose most likely resulting in maintenance | 0.5 mg. | 0.1 mg. | 1.0 mg. |
| Daily undivided dose most likely resulting in toxicity | 1.0 mg. | 0.2-0.3 mg. | 1.5-2.0 mg. |
| Ease of achieving maintenance | Good | Good | Fair |
| Ease of predicting dose | Good | Good | Trial and error |
| Dissipation | Rapid | Slow | Rapid |
| Duration of toxicity | Short | Long | Short |

Speed of Action of Digitalis Preparations Given Intravenously

| | *Action Starts* | *Full Effect* |
|---|---|---|
| Ouabain | Few minutes | 1 hour |
| Cedilanid | 15-30 minutes | 2 hours |
| Digilanid | 3 hours | — |
| Digitoxin | 3 hours | 6 hours |

chloride may be administered in order to correct this condition) (5) In some patients the administration of 10 per cent glucose is also helpful and in others the administration of aminophylline or decholin before the diuretic is very helpful in restoring the effectiveness of the mercurial (6) Peritoneal lavage has been recommended but this is a rather dangerous procedure It should be used only as a last resort It is important to remember that, if several doses of the mercurial diuretic have been given and no diuresis has been obtained it is usually dangerous to administer the drug further for its retention in the body may produce toxic mercurial symptoms

*Other Diuretics* —Other diuretics may be used alone or as an adjuvant to therapy with the mercurials Ammonium chloride 3 to 8 grams a day, may be used but it is usually not necessary The xanthine group of drugs is occasionally used for diuretic effect however, they rarely by themselves suffice in the treatment of congestive heart failure If used they may be given as theobromine sodium acetate 0 5 grams three times a day or theophylline ethylene diamine 0 5 gram three to five times a day or theobromine calcium salicylate 0 5 grams three to five times daily Urea in a dose of 20 grams, may be administered from 2 to 5 times a day Because it is difficult to take by itself it is usually given with fruit juices iced fluids, or syrup

*Dietary Regimen —Salt and Water Intake* —A salt poor diet low in calories is preferred during the initial stage of heart failure For this purpose, the Karrell diet may be used This consists of 1000 cc of milk a day the milk contains 1 gram of salt The patient is put on this diet for a few days or a week, after satisfactory diuresis has resulted the caloric content of the diet may be raised and further foods added The fluid intake may then be increased to from 2000 to 3000 cc a day and the salt intake to 2 grams The importance of a salt poor diet cannot be overemphasized The normal daily diet contains about 10 grams of salt Patients with heart failure can eliminate only about 2 or 3 grams of salt a day The usual salt poor diets contain 5 or 6 grams of salt The salt which cannot be eliminated is retained in the body and produces edema The best way is to keep a patient on a dietary regimen of about 1½ grams of salt a day is to examine every dietary item to be given that patient and make sure that it is salt free Even salt free bread may be obtained Salt substitutes may be used to make the diet more palatable There are a number of such substances available such as neo curtisal diasal and chlor salt On the type of low-sodium diet described here, the patient may take fluids up to 3000 or 4000 cc a day without danger of water retention The water intake should be approximately 1 0 or 1 5 cc for each calorie ingested If the water intake is inadequate casts albumin and red blood cells will appear in the urine and the urea nitrogen level will rise It is therefore essential that the water intake be adequate and the sodium as low as possible

*Cation Exchange Resins* —Recently cation-exchange resins have been developed in an effort to reduce sodium retention without forcing the patient to live on an unpalatable diet These resins are insoluble acids capable of removing basic ions from solutions with which they come in contact Exchange resins have the disadvantage however of causing gastrointestinal irritation acidosis and depletion of potassium calcium and magnesium But the gastric irritations may be decreased by using carboxylic instead of sulfonic types of resins and ammonium instead of hydrogen exchangers Further if potassium is added to the resins the danger of potassium depletion is minimized

These exchange resins by absorbing sodium from the gastrointestinal tract and carrying it in to the feces permit the patient to have more sodium in his diet Nevertheless the patient with heart failure must not have more than 3 to 5 grams of sodium a day even though he is taking such a resin The usual dose of the carboxylic resin with potassium is 15 grams 3 or 4 times daily The dosage of course often needs adjustment in the individual case Further to be certain that complications from electrolyte deficiencies do not occur electrolyte studies must be performed at regular intervals

*Removal of Effusions* —Removal of pleural effusions and ascitic fluid may indirectly

help the heart and enable diuretics and digitalis to act more efficiently. Pericardial effusions resulting from congestive heart failure are usually not large enough to require paracentesis. But where pericardial effusions are great and heart failure results it is advisable to remove the effusion in order to increase cardiac efficiency. In the occasional patient with marked edema of the extremities Southey tubes may be used to help drain off the excess fluid.

### Digitalis in Heart Failure

*Preparation and Dosage.*—Many preparations of digitalis drugs and their glycosides are available for the treatment of heart failure. Speed of Action of Digitalis Preparations Given Intravenously

| | *Action Starts* | *Full Effect* |
|---|---|---|
| Ouabain | Few minutes | 1 hour |
| Cedilanid | 15-30 minutes | 2 hours |
| Digilanid | 3 hours | — |
| Digitoxin | 3 hours | 6 hours |

The following patients develop toxic effects on the smaller dose and should be given digitalis with care: patients with aortic stenosis, those manifesting a severe grade of myocardial damage, those with overactive vagal tone, those in the older age group, and those having a fresh myocardial infarction.

The maintenance dose of the digitalis drugs also varies considerably in different patients and at different times in the same patient. It is suggested that after digitalization the average dose for maintenance be given the patient. The patient should not be kept on this dose indefinitely but should be frequently checked up on and the dose increased or decreased, depending on the patient's need and response.

Recently, the trend has been to administer the pure glycosides, such as digitoxin, digoxin, cedilanid, and lanatoside C, or a combination of these glycosides, such as digilanid, rather than the powdered leaf. The advantages of this are the smaller required dosage, the greater accuracy in standardizing the drug, and the absence of local irritating effects on the gastrointestinal tract. The action of these purified preparations, however, is not always exactly the same as that of the powdered leaf. The purified preparations vary in the degree of muscular and vagal effect they have, and the dosages, even for patients with auricular fibrillation, are difficult to compare with those of the powdered leaf. But by digitalizing the patient as outlined and by giving an adequate maintenance dose and observing the patient for the desired as well as toxic effects, almost any of these preparations can be used successfully.

*Parenteral Administration.*—The intravenous administration of digitalis drugs is indicated when the maintenance of a rapid effect is mandatory and oral administration is considered slow and undependable, as for example in severe cases of advanced heart failure after the occurrence of rapid auricular fibrillation or flutter. In some of these cases intravenous administration of the drug has dramatic and almost immediate effects. An effect from strophanthin may be obtained as early as five minutes after administration. It is important to remember, however, that, if the intravenous route is used, the danger of toxicity is increased. This route should not be used if the patient has received digitalis during the previous two weeks. It is safest to administer half the intravenous digitalizing dose and wait half an hour or an hour, in order to note the effect of the initial dose; additional doses may then be given either orally or intramuscularly, which is much safer. Ouabain, strophanthin and cedilanid not only act rapidly but are dissipated rapidly, so that, after the full effect is obtained, digitalization by mouth may be begun.

The intramuscular route is also indicated if the need for haste is not so urgent as that mentioned above but relatively rapid and dependable absorption of the drug desired.

*Tolerance.*—The tolerance for digitalis varies considerably with the age of the patient, the type and severity of the heart condition, and the absence or presence of heart failure. In general it may be said that older patients and those with greatly damaged hearts show decreased tolerance to digitalis and manifest a very narrow range between therapeutic and toxic effects. In such patients, toxic effects may occur long before maximum therapeutic effects appear. Patients with acute myocardial infarction apparently cannot tolerate the same amount of the drug as other heart patients. Patients with partial A-V block and those with aortic stenosis are apparently more susceptible to the development of increasing degrees of heart block on relatively small doses of the drug. In some cases of partial auriculoventricular block, however, the use of digitalis has so improved the myocardial efficiency that the block disappears entirely when the heart failure disappears. This, though, is rather rare.

*Toxicity.*—The most important symptoms of the untoward effects of digitalis are malaise, headache, anorexia, nausea, vomiting, diarrhea, and occasionally psychoses and eye symptoms. The initial symptoms—malaise, headache, and anorexia—may be obscured by the underlying cardiac state, but nausea and vomiting are fairly dependable signs of toxic effect. It is well to remember, though, that when the powdered leaf is given, nausea and vomiting may result from a local irritating effect of the drug on

the gastric mucous membrane When this is the case purified preparations are administered It should be emphasized that vomiting is not invariably present with digitalis toxicity The electrocardiogram may show extremely dangerous evidence of such toxicity though neither nausea nor vomiting has occurred This is especially true in advanced cases of heart disease and in senile patients In such cases marked weakness and asthenia with clear-cut evidence of toxicity as shown by dangerous cardiac irregularities often occur instead of nausea and vomiting The cardiac manifestations are often more dependable signs of *digitalis toxicity than vomiting or diarrhea*

Though as stated above the vomiting produced by digitalis may be due to local irritation of the mucosa of the gastrointestinal tract a more common cause of it is the action of the drug on the medulla where there is an increase in irritability This increase in irritability of the medulla makes the 'vomiting center' respond to stimuli which might otherwise be of no significance The diarrhea produced by digitalis overdosage is also more often a central nervous system phenomenon than the result of local irritation Psychoses observed in cases of digitalis toxicity are apparently due to a concommitant cerebral circulatory disturbance rather than to a direct effect of the drug but this has not been finally decided Eye symptoms—spots and various colors such as green blue and yellow before the eyes—are often occasioned by digitalis toxicity but these are usually temporary and disappear with discontinuance of the drug These eye findings are believed to result from direct toxic effects of the drug on the primary optic centers in the brain Digitalis should be stopped when (1) the heart rate drops to 60 or below (2) a regular pulse becomes irregular (3) a bigeminal rhythm develops or (4) the cardiac rate previously between 80 and 100 suddenly becomes rapid or rapid and irregular with a rate of from 140 to 180 beats a minute

The electrocardiographic evidence of digitalis effects consists of characteristic alterations of the T waves and the ST segments The ST segments in leads 1 2 and 3 and the precordial leads are depressed and show a bowing or sagging with the concavity upward This bowing may drop the ST segments several millimeters below the base line This may then cause the T waves to be diphasic or even inverted Often however the T waves will show only flattening The PR interval becomes prolonged and heart block of various grades may result In some electrocardiograms, several of these evidences of the drug's action may be observed in one tracing Most of these electrocardiographic alterations are likely to occur within the therapeutic range of digitalis action The presence of the following however, are *unequivocal signs of toxicity* (1) high-grade A-V heart block becoming complete heart block, (2) A V dissociation with ventricular escape (3) numerous ventricular extrasystoles (4) coupled rhythm (5) auricular tachycardia with A-V heart block and (6) ventricular tachycardia The treatment of these ectopic rhythms consists in stopping the digitalis Quinidine and procaine amide may be of help in correcting the ventricular extrasystoles coupled rhythms, and ventricular tachycardias

*Treatment of Acute Left Heart Failure* —In treating acute left heart failure the underlying heart condition (such as coronary artery disease aortic or mitral valvular disease or hypertension) must be corrected certain reflexes must be abolished rapid ectopic rhythms (which may have precipitated the attack) must be eliminated and the circulating blood volume must be decreased so that the damaged heart can work with less strain

(*a*) *Treatment During Attack* —During the attack the patient is usually much more comfortable in a sitting or upright position The initial therapeutic procedure is the administration of morphine sulphate, 15 mgm given alone or with atropine 0 4 to 0 8 mgm The morphine sulphate may be given subcutaneously intramuscularly, and at times (during a shock like state) intravenously The earlier this is given after the beginning of an attack the better the therapeutic result will be In many patients administration of this drug alone will abort the attack in 10 or 15 minutes In older patients who are sensitive to the effects of morphine the

The following patients develop toxic effects on the smaller dose and should be given digitalis with care: patients with aortic stenosis, those manifesting a severe grade of myocardial damage, those with overactive vagal tone, those in the older age group, and those having a fresh myocardial infarction.

The maintenance dose of the digitalis drugs also varies considerably in different patients and at different times in the same patient. It is suggested that after digitalization, the average dose for maintenance be given the patient. The patient should not be kept on this dose indefinitely but should be frequently checked up on and the dose increased or decreased, depending on the patient's need and response.

Recently, the trend has been to administer the pure glycosides, such as digitoxin, digoxin, cedilanid and lanatoside C, or a combination of these glycosides, such as digilanid, rather than the powdered leaf. The initial symptoms—malaise, headache and anorexia—may be obscured by the underlying cardiac state, but nausea and vomiting are fairly dependable signs of toxic effect. It is well to remember, though, that when the powdered leaf is given, nausea and vomiting may result from a local irritating effect of the drug on

some of them offer a certain degree of hope An operation to diminish the strain on the left auricle consists in anastomosing one branch of the pulmonary vein to the azygous vein This results in a short-circuiting of some of the blood from the left auricle to the systemic venous circulation It results, in effect in a recirculation of blood but though it may partially reduce the strain on the left auricle it is doubtful whether this is the final answer to the problem

*Adherent Pericardium in Constrictive Pericarditis* —Adherent pericardium in constrictive pericarditis may result in heart failure (and failure of diastolic filling) Removal of the adhesions around the body of the heart and inferior vena cava has resulted in some cases in cure of the heart failure When this is the cause the treatment may produce miraculous results

*Supplementary Therapeutic Measures* —*Nutrition* — Poor nutritional states may aggravate at times, and precipitate heart failure The correction of such states is advised by dietotherapy treatment for anemia or the use of blood and plasma

*Chemotherapy and Antibiotics* — Infectious states may also aggravate or precipitate heart failure These states may be treated with chemotherapeutic and antibiotic agents The prophylactic use of sulfonamides and penicillin in rheumatic carditis will help prevent heart failure

*Treatment of Metabolic Disorders* —The adequate treatment of diabetes particularly the coma and the acidosis is important since the coma and the acidosis of diabetes have deleterious effects on the heart also uncontrolled diabetes hastens the development of arteriosclerosis

*Treatment of Electrolyte Changes* —Alterations in the electrolytes are observed in a variety of conditions as in inanition after surgery vomiting and diarrhea in renal disease and in various metabolic disorders The effects of a low serum sodium level have already been discussed Hypocalcemia increases the irritability of the heart muscle A low serum potassium level results in a disturbance of the function of the already diseased heart Patients with heart failure who respond poorly to the usual therapy will show improvement when the electrolyte picture is corrected

*Climate* —Patients subject to congestive heart failure do best in a mild climate They do not do well in hot weather this is probably the result of an increase in cardiac output loss of electrolytes and excessive thirst with difficult elimination of water Air conditioning in hot weather greatly helps such patients Cold weather also increases the work of the heart especially by increasing peripheral resistance and so may precipitate a bout of congestive failure

respirations may drop to 10 or less a minute In such patients it is well to administer with the morphine a respiratory stimulant such as caffeine coramine or metrazol Digitalization if the patient has not had any digitalis for two weeks or more, may be accomplished rapidly by intravenous administration of strophanthin 0 6 to 1 2 mgm or cedilanid, 0 8 to 1 6 mg If less haste is required, digalin may be given intramuscularly in a dose of from 3 to 5 cat units Generally however digitalization is less efficacious than the other procedures mentioned for the treatment of the acute attack

Caffeine with sodium benzoate 0 5 grams may be given initially and repeated every 2 or 3 hours for about 3 doses This acts as a respiratory and cardiac stimulant Coramine 1 cc may be repeated 2 or 3 times over a period of 2 or 3 hours Aminophylline 0 3 gram may be given slowly intravenously in a 200 cc drip of 5 per cent glucose and may be repeated in about one hour The beneficial effects of this drug depend on its action as a respiratory stimulant and, possibly as a coronary dilator

Oxygen may be given by nasal catheter mask or tent it may be necessary to give it under positive pressure The administration of oxygen is very important in left heart failure since the heart suffers five times as much from lack of oxygen as does skeletal muscle The maintenance of the maximum degree of oxygenation is important for the optimum function of the heart particularly when the pulmonary vascular field available for oxygenation is diminished as it is in left heart failure

In the plethoric patient with distended veins, venesection of from 250 to 500 cc of blood is of help in rapidly reducing the strain on the left side of the heart This should not be done if the patient is asthenic has experienced frequent attacks of heart failure is anemic or does not have distended veins A bloodless venesection may be accomplished by the application of tourniquets to all four extremities These should be tight enough to prevent venous return but not tight enough to prevent the inflow of arterial blood These may be kept on for 10 or 15 minutes then one extremity at a time is released in rotation This regimen is of as much help in reducing the circulating blood volume as is venesection Though the administration of 50 per cent glucose or sucrose has been recommended for the treatment of pulmonary edema, because of their osmotic effect it is not considered a safe procedure

After the attack of left heart failure the patient should be kept at rest in bed for one or two days Frequently, the patient feels quite well the morning after the attack and is often able to go about his work It is advisable however, to watch such a patient for he may develop a mild bronchopneumonia This usually yields to the antibiotics

(b) *Prophylactic Measures in Patients Subject to Attacks of Left Heart Failure* —The following measures will help prevent recurrent attacks of left heart failure (1) bed rest (2) restriction of sodium intake and correction of fluid intake, (3) digitalization, (4) administration of mercurial diuretics (one injection every week or two or more frequently as indicated by the patient s weight-curve and clinical signs and symptoms as previously outlined these diuretics may be given with or without ammonium chloride two or three grams a day (5) light supper with little fluid before bedtime instead of heavy meals (6) raising the head of the patient s bed 8 or 9 inches from the floor (7) administration of aminophylline 0 2 grams 3 times a day by mouth and/or 0 67 grams rectally at bedtime (other drugs of the xanthine series may be used with equal effect) (8) administration of sedatives preferably the barbiturates (9) prevention of abdominal distention by careful regulation of the bowels and food intake (10) reduction regimen for obese patients (11) careful evaluation of the patient s daily activities in order to outline a routine to reduce heart strain to a minimum

*Surgical Treatment of Heart Failure* —Various surgical procedures have been suggested for the treatment of congestive heart failure Essentially these are attempts to relieve the strain on the heart

Valvulotomies and valvuloplasties as well as commissurotomies have been performed in the presence of mitral stenosis These operations involve considerable risk but

some of them offer a certain degree of hope An operation to diminish the strain on the left auricle consists in anastomosing one branch of the pulmonary vein to the azygous vein This results in a short circuiting of some of the blood from the left auricle to the systemic venous circulation It results in effect in a recirculation of blood, but though it may partially reduce the strain on the left auricle it is doubtful whether this is the final answer to the problem

*Adherent Pericardium in Constrictive Pericarditis* — Adherent pericardium in constrictive pericarditis may result in heart failure (and failure of diastolic filling) Removal of the adhesions around the body of the heart and inferior vena cava has resulted in some cases in cure of the heart failure When this is the cause the treatment may produce miraculous results

*Supplementary Therapeutic Measures — Nutrition* —Poor nutritional states may aggravate at times, and precipitate heart failure The correction of such states is advised by dietotherapy, treatment for anemia or the use of blood and plasma

*Chemotherapy and Antibiotics* —Infectious states may also aggravate or precipitate heart failure These states may be treated with chemotherapeutic and antibiotic agents The prophylactic use of sulfonamides and penicillin in rheumatic carditis will help prevent heart failure

*Treatment of Metabolic Disorders* —The adequate treatment of diabetes particularly the coma and the acidosis is important since the coma and the acidosis of diabetes have deleterious effects on the heart, also uncontrolled diabetes hastens the development of arteriosclerosis

# THE HEART IN SPECIAL CONDITIONS

## HEART DISEASE AND PREGNANCY

BY GEORGE DAVID GECKELER M D
and WILLIAM LIKOFF M D

THE importance of heart disease in pregnancy is reflected in the fact that it is estimated that 2 per cent of all prenatal patients have some form of cardiac disorder The mortality in that group is five times as great as in patients with normal hearts Viewed from a different statistical standpoint heart disease accounts for 25 per cent of all maternal deaths

Whether it is safe for a woman with a cardiac ailment to bear children may be a difficult decision to make. To appraise the problem, the physician must have full knowledge of the nature and severity of the heart lesion. He must understand the essential changes which occur in the circulation during pregnancy, how they may simulate organic heart disease, and the manner in which they may compromise the function of an impaired cardiovascular system.

That is by no means the full task. To conclude the problem successfully, he must be prepared to supervise the patient constantly, seeking out the signs and symptoms of impending trouble. When these are discovered, he must be prepared to treat them with definitive measures.

Only with knowledge, skill, and seasoned judgment are the problems presented by diseases of the heart and pregnancy adequately defined and met. The final estimate of success is in the reduction of maternal and fetal mortality.

*The Circulation in Pregnancy*.—The most significant change in the circulation during pregnancy is the increase in cardiac output. This amounts to approximately 50 per cent in minute volume at the time the output is at its greatest magnitude.

It was formerly believed that the burden on the circulation increased steadily and reached its peak at term, but it has now been demonstrated that the increase in cardiac output is not great before the twelfth week. From that point it rises gradually until the 24th week, and then more abruptly until the 32nd or 36th week, when it lessens to half its rise. Although exactly when the reducing of the burden takes place is not identically fixed by all investigators, there is complete agreement on the cyclic increase and decrease is output *before* term.

Associated with these changes are parallel alterations in blood volume and circulation rate. The average increase in blood volume is 45 per cent and is accounted for by an increase in the plasma volume. The progressive dilution of blood reaches its peak approximately in the 32nd week, after which it gradually returns to more normal values. A corresponding fluid retention takes place in the tissues. Since a positive salt balance has been demonstrated during gestation and a negative balance during the latter weeks of pregnancy and in the puerperium, it is probable that this alteration accounts for the water retention in both the blood and extracellular fluids.

Although a moderate elevation in arterial pressure and cardiac output is observed during labor, the increased burden on the circulation at that time is less than when the output is at its maximum level during pregnancy.

Changes also occur in pulmonary function. The respiratory reserve falls during pregnancy as the result of a 50 per cent increase in pulmonary ventilation. This is accompanied by an increase in respiratory excursions, although actually oxygen consumption is only from 15 per cent to 20 per cent greater than normal. Because of an increase in the transverse diameter of the chest, which overcompensates for the elevation of the diaphragm, a slight increase in the vital capacity of the lungs is observed.

The critical fact in these physiologic alterations in the circulation during pregnancy is that the increase in burden reaches its peak *before* term and is dependent upon rises in cardiac output and blood volume. The mechanism for the increase in blood volume is not fully understood, but the retention of salt and water is an important factor. *The clinical manifestations found in pregnant cardiacs stem from those changes which are common to all child-bearing patients.*

*Types of Heart Disease Found in Pregnancy*.—The types of heart disease seen in pregnancy are those observed in any group of young adults. More than 90 per cent are the result of rheumatic activity. Mitral stenosis is the most common lesion and in combination with aortic disease is more usual than aortic involvement alone or any other combined valvular damage.

In a series of 437 cases Jones found that 6.8 per cent of the patients had congenital heart disease and 2.1 per cent hypertensive cardiovascular disease. These figures approximate those of Hamilton. Cardiac disorders caused by arteriosclerosis, syphilis and thyrotoxicosis are not commonly met

(they make up on the average only one per cent of the total)

In view of the tremendous strides made by cardiac surgery in recent years the opportunity will shortly be offered of supervising young women who have had congenital heart defects corrected by surgery and who have for example, undergone such a procedure as mitral commissurotomy Experience is also increasing with patients who have become pregnant after recovering from subacute bacterial endocarditis

*The Diagnosis of Heart Disease in Pregnancy* —Certain cardiovascular signs and symptoms develop with any ordinary gestation They are similar to those observed in any patient with a hyperkinetic heart and must be differentiated from the more specific clinical features of organic cardiac disease

*Palpitation* is an extremely common complaint It occurs independent of activity and is very often caused by numerous premature systoles which originate in the atrium or ventricle Atrial fibrillation is an exceptionally uncommon arrhythmia in normal pregnancy and its presence almost always indicates serious heart disease

*Dyspnea* is reported by more than half of all normal pregnant women It is actually the result of the increased pulmonary ventilation which occurs even at rest This is never accompanied by fine basal rales cough the production of frothy sputum or a fall in vital capacity

*Tachycardia* is not marked in normal pregnancies although the patient may be conscious of the acceleration of the pulse rate which averages from ten to twenty beats a minute Generally the hyperkinetic action of the heart is misinterpreted by the patient as a tachycardia

*Edema* of the lower extremities is usual in 50 per cent of all normal pregnancies It is the result of salt and water retention and the compression of the pelvic veins by the enlarged uterus

*Pain* over the precordial area is an unexplained symptom It is usually sharp and of short duration and occurs mainly at rest It may well disappear when the patient is gainfully occupied

The *apical impulse* of the heart may be dislocated upward and outward and, because of its position simulate cardiac enlargement Inasmuch as this finding is rarely the sole basis for a diagnosis of heart enlargement serious confusion rarely results

The *first heart sound* is loud at the apex in normal pregnancies The intensity may be similar to that heard in thyrotoxicosis At the second left interspace, the second heart sound is also usually accentuated

*Murmurs* are heard in more than 50 per cent of all normal women who are pregnant The murmurs are usually blowing systolic murmurs generally grade one or two and may be heard at the apex or more often at the base of the heart It must be emphasized that such normal murmurs are blowing highly localized and systolic They frequently disappear with a change in the depth of respiratory excursions or with alterations in body position and posture

A *third heart sound* may be heard in normal pregnancies It may occur in any adult with hyperkinetic heart action Its importance depends on whether it can be differentiated from a gallop rhythm with a rapid heart rate and from the opening snap of mitral stenosis

The *roentgen examination* of the normal heart in pregnancy may at times give rise to some confusion The postero-anterior view may reveal an apparent straightening of the left border, a condition mimicking the silhouette of mitral stenosis Furthermore in the right anterior oblique position the left atrium may appear enlarged These findings are satisfactorily eliminated by x raying the patient at the height of inspiration Although the cardio-thoracic ratio is not entirely reliable under any circumstances it may be greater than the 50 per cent critical value in normal pregnancies since the transverse diameter of the heart is increased by the elevation of the diaphragm

The *electrocardiogram* may reveal a shift in the electrical axis to the left and a negative $T_3$ accompanied by a deep $Q_3$ This is the result of the horizontal position of the heart and is not commonly confused with the changes observed in coronary-artery disease

Whether it is safe for a woman with a cardiac ailment to bear children may be a difficult decision to make. To appraise the problem, the physician must have full knowledge of the nature and severity of the heart lesion. He must understand the essential changes which occur in the circulation during pregnancy, how they may simulate organic heart disease, and the manner in which they may compromise the function of an impaired cardiovascular system.

That is by no means the full task. To conclude the problem successfully, he must be prepared to supervise the patient constantly, seeking out the signs and symptoms of impending trouble. When these are discovered, he must be prepared to treat them with definitive measures.

Only with knowledge, skill and seasoned judgment are the problems presented by diseases of the heart and pregnancy adequately defined and met. The final estimate of success is in the reduction of maternal and fetal mortality.

*The Circulation in Pregnancy.*—The most significant change in the circulation during pregnancy is the increase in cardiac output. This amounts to approximately 50 per cent in minute volume at the time the output is at its greatest magnitude.

It was formerly believed that the burden on the circulation increased steadily and reached its peak at term, but it has now been demonstrated that the increase in cardiac output is not great before the twelfth week. From that point it rises gradually until the 24th week and then more abruptly until the 32nd or 36th week, when it lessens to half its rise. Although exactly when the reducing of the burden takes place is not identically fixed by all investigators, there is complete agreement on the cyclic increase and decrease is output *before* term.

Associated with these changes are parallel alterations in blood volume and circulation rate. The average increase in blood volume is 45 per cent and is accounted for by an increase *in the plasma* volume. The progressive dilution of blood reaches its peak approximately in the 32nd week, after which it gradually returns to more normal values. A corresponding fluid retention takes place *in the tissues*. Since a positive salt balance has been demonstrated during gestation and a negative balance during the latter weeks of pregnancy and in the puerperium, it is probable that this alteration accounts for the water retention in both the blood and extracellular fluids.

Although a moderate elevation in arterial pressure and cardiac output is observed during labor, the *increased burden on the circulation* at that time is less than when the output is at its maximum level during pregnancy.

Changes also occur in pulmonary function. *The respiratory reserve falls during pregnancy* as the result of a 50 per cent increase in pulmonary ventilation. This is accompanied by an increase in respiratory excursions, although actually oxygen consumption is only from 15 per cent to 20 per cent greater than normal. Because of an increase in the transverse diameter of the chest, which overcompensates for the elevation of the diaphragm, a slight increase in the vital capacity of the lungs is observed.

The critical fact in these physiologic alterations in the circulation during pregnancy is that the increase in burden reaches its peak *before* term and is dependent upon rises in cardiac output and blood volume. The mechanism for the increase in blood volume is not fully understood, but the retention of salt and water is an important factor. The clinical manifestations found in pregnant cardiacs stem from those changes which are common to all child bearing patients.

*Types of Heart Disease Found in Pregnancy.*—The types of heart disease seen in pregnancy are those observed in any group of young adults. More than 90 per cent are the result of rheumatic activity. Mitral stenosis is the most common lesion and in combination with aortic disease is more usual than aortic involvement alone or any other combined valvular damage.

In a series of 437 cases Jones found that 6.8 per cent of the patients had congenital heart disease and 2.1 per cent hypertensive cardiovascular disease. These figures approximate those of Hamilton. Cardiac disorders caused by arteriosclerosis, syphilis and thyrotoxicosis are not commonly met

materially impaired This is not the general feeling Along with Hamilton, Maynard believes that atrial fibrillation has the same ominous meaning as congestive heart failure and that it increases the risk of death in pregnancy fourfold

4 *The Degree of Cardiac Enlargement* — In no sense is the extent of cardiac enlargement alone an accurate guide to the severity of heart disease Similarly the absence of enlargement is not an indication that a patient will successfully pass through pregnancy

5 *The Presence of Active Rheumatic Infection* —Active rheumatic fever is most uncommon in pregnant patients When it does occur however, particularly in the first trimester a termination of the pregnancy is advisable If the pregnancy is far advanced continuation is safer than interruption

6 *The Presence of Subacute Bacterial Endocarditis* —With the introduction of antibiotics subacute bacterial endocarditis discovered during pregnancy can be successfully treated The death rate may be somewhat higher for pregnant women with subacute bacterial endocarditis, but there is no evidence that a patient who has been cured of the disease successfully will develop a recurrence of it during later pregnancies

7 *Hypertension* —An elevation in the arterial blood pressure is not a serious complication of pregnancy in patients who have cardiac heart disease It does however increase the hazard of toxemia Furthermore, there is evidence that the hypertension in itself may be accelerated by the pregnancy

8 *The History of Prior Heart Failure* — A history of congestive heart failure makes future pregnancy as risky as does the presence of heart failure This is particularly true if acute pulmonary edema has occurred

9 *Hemoptysis* —This is usually the result of pulmonary infarction or pulmonary hypertension In either case it is a contraindication to pregnancy Only in the rare instance when hemoptysis occurs following peripheral venous thrombosis that has been adequately treated is pregnancy to be considered

10 *Parity* —There is little evidence to suggest that parity has any influence on the prognosis of a pregnancy provided the patient s condition has not materially altered between pregnancies It should be emphasized, however, that the care of a child is more difficult for the older woman particularly when previous offspring demand their allotment of time and energy When a family is complete and the maternal health has been safeguarded through several pregnancies, it seems unwise to encourage further childbearing that will demand a greater expenditure of cardiac reserve at an age when it can be least spared

In patients with congenital heart disease the acyanotic tolerate pregnancy well It appears that the greater the degree of cyanosis the more uncertain the prognosis Coarctation of the aorta affords particular concern in the acyanotic group because of the risk of rupture of the aorta acute left ventricular failure and cerebral hemorrhage These are more likely to occur during labor than during gestation

If cardiac function is adequate pregnancy is not clearly harmful to patients with hypertensive and arteriosclerotic heart disease There is adequate evidence however that hypertension may be accelerated by pregnancy Patients with severe hypertension and azotemia are considered poor risks and in the same category as those with congestive heart failure resulting from rheumatic heart disease Although coronary heart disease is extremely rare in pregnant women, it is a firm contraindication to pregnancy

Of the infrequent cases of syphilitic heart disease complicated by pregnancy aortic regurgitation is most common This is recognized as a severe complication Cases however have been reported in which pregnancy was successfully completed in the presence of marked aortic regurgitation In this lesion as in others all influencing factors and the state of compensation must be evaluated before pregnancy is permitted

*The Management of the Pregnant Cardiac Patient* —The patient with heart disease should be advised as early as possible whether future pregnancy is advisable Under those circumstances when pregnancy

With a clear knowledge of the cardiovascular signs and symptoms in ordinary pregnancies, the diagnosis of organic heart disease is greatly simplified

In every instance, an accurate diagnosis should be made in conformity with the standards of the American Heart Association

The *history* is only a partial guide to the presence of rheumatic heart disease, inasmuch as 50 per cent of the patients with rheumatic heart disease have no knowledge of having had an attack of rheumatic fever When the history is positive it aids in classifying the patient in relation to the natural progress of the disease Thus, the number of attacks of rheumatic fever, their severity, and the time of their occurrence in relation to the pregnancy are critical bits of information It is important that congestive heart failure paroxysmal tachycardia embolic phenomenon, subacute bacterial endocarditis and hemoptysis be searched for in the history Finally in view of the impending increased burden upon the circulation, it is essential to investigate how competently the patient has been able to withstand the rigors of ordinary living

Since the patient is in the younger age group and subjective symptoms of cardiac embarrassment may not yet be present a proper diagnosis may rest solely upon the objective examination *The discovery of a valvular lesion may be the only evidence of rheumatic heart disease*

In many cases of mitral stenosis the mid late diastolic murmur with or without presystolic accentuation may not be heard when the patient is at rest This emphasizes the importance of examining the patient after brief but vigorous exercise Even after exercise the murmur may be highly localized and heard only in the left lateral position when the breast is held to one side

Other important auscultatory features may be heard in mitral stenosis The first heart sound may be sharp *i e*, short and high pitched this is to be differentiated from the loud first heart sound of normal pregnancies When it is accompanied by an accentuated pulmonic second sound the physician should be particularly alert in his search for a mid late diastolic murmur On the other hand, the opening snap of a mitral stenosis may be heard This must be differentiated from a normal third heart sound Although the opening snap does not necessarily bear a closer time relation to the second heart sound, it is of uniformly greater intensity than the normal third sound and is usually accompanied by an accentuated pulmonic second sound and a mitral systolic murmur The differentiation between the opening snap of mitral stenosis and gallop rhythm with tachycardia may be extremely difficult, other features, however may help the physician to make it

The murmurs of congenital heart lesions may be so impressive that they can not be overlooked in the most casual physical examination Often, however major defects such as the tetralogy of Fallot or large septal defects, exist without loud murmurs In such cases, investigation for cyanosis and clubbing of the fingers is of great importance

The cardiac examination during pregnancy should include (1) a roentgen survey for heart size and contour and (2) an electrocardiogram These procedures occasionally point to heart disease that is not readily apparent

*Significant Factors in the Pregnant Cardiac* —The greatest cause of death when pregnancy accompanies structural heart disease is heart failure, and the most common type is pulmonary edema Embolic phenomenon and subacute bacterial endocarditis are much less frequently fatal Therefore the most important factor which makes for a successful pregnancy is the state of cardiac compensation

1 *Age* —Rheumatic cardiacs are more likely to develop congestive heart failure in pregnancy as they become older

2 *Duration of Heart Disease* —As the interval of time lengthens from the onset of rheumatic fever to pregnancy the incidence of such failure rises

3 *The Presence of Atrial Fibrillation* —This arrhythmia implies that the heart disease is both long standing and severe In its presence the risk of pregnancy is grave Jones believes however that the arrhythmia itself is not a complication of pregnancy and suggests that pregnancy may be allowed if the capacity for effort is not

cardiovascular apparatus may fail with time The economic status of the patient the completeness of the family the personality of the mother and the manner in which she reacts to children are all factors entering into the problem

*Patients Unfit for Pregnancy* —When a cardiac patient who is unfit for pregnancy is seen in the first trimester interruption of pregnancy should be advised This termination should not take place in the face of acute congestive heart failure or other serious illness Under all circumstances the heart must be compensated before abortion is attempted

In the second trimester, an interruption of pregnancy is rarely indicated When heart failure is present in the early part of the second trimester and the response to therapy has not been adequate interruption of the pregnancy may be advisable since the patient is still faced with months of a progressive burden on the circulation This problem is an extremely difficult one and entails grave risk

In the third trimester interruption of the pregnancy is rarely indicated the load on the circulation will decrease with time and medical control is more likely to succeed

In any or all circumstances the mode of termination is a problem for the obstetrician

*Treatment of Heart Failure* —The treatment of heart failure in the pregnant patient is along the usual lines When acute pulmonary edema is present (in view of the fact that it is due at least in part to an increase in blood volume), rapid venesection may be indicated The use of morphine and oxygen and intravenous digitalis preparations is fundamental and may clear up an ominous clinical state

Chronic congestive heart failure is best treated by gradually increasing rest as the load on the circulation increases This rest is preferable in the semi recumbent position in order to shift fluid concentrations to the extremities A diet low in salt (1 2 Gm of salt a day) is strongly recommended Once digitalis is used it should be continued throughout the pregnancy Although there is some danger in using the mercurial diuretics in pregnancy in which there is always the possibility of renal damage the drugs are not to be withheld when indicated Finally the salt absorbing resins may greatly aid in keeping the patient upon a salt poor routine

*Confinement* —The mode of delivery is subject to the judgment of the obstetrician Hamilton and Thomson have shown that, among cardiac women the mortality in vaginal delivery is 2 3 per cent as compared to 8 3 per cent for abdominal deliveries

With coarctation of the aorta a catastrophic accident may occur during labor and abdominal delivery may be advisable particularly when the patient is over thirty years of age

A trial of labor is rarely indicated in the presence of heart disease The manner of delivery should be decided upon well in advance and the patient properly prepared in order to avoid the hazards which accompany indecision

*Post Partum Care and Future Pregnancies* —Convalescence from pregnancy is determined by the severity of the cardiac lesion As a general rule, when the cardiac condition is marked the convalescence should be prolonged The state of compensation determines the degree of activity A woman who has once been in congestive heart failure is never a candidate for future pregnancy

is possible but not desired, the patient should be instructed to have her physical condition thoroughly reviewed before pregnancy is contemplated When pregnancy occurs before re evaluation has been made, the patient should be re-examined as soon as possible

In women with heart disease fitness for pregnancy can best be determined by an analysis which enables one to place the patient in a functional classification as suggested by the American Heart Association Patients who have no limitation of activity (Class I) rarely if ever, have a serious complication in pregnancy In the series recorded by Pardee no deaths occurred among 157 pregnant women with this functional capacity Patients who have slight or moderate limitation of activity (Class II) seldom develop serious complications either But patients who have from moderate to great limitation of activity (Class III) frequently fail to survive pregnancy and patients unable to carry on any physical activity without embarrassment (Class IV) commonly die in pregnancy

This functional classification should be augmented by an analysis of other factors which materially affect the outcome of the pregnancy

*Patients Fit for Pregnancy* —The basis of the management of heart disease during pregnancy is the prevention of heart failure If this is not possible emphasis must be placed on early diagnosis of the failing heart and on efficient treatment Most pregnant women with heart disease will do well provided careful examinations are carried out every month for the first seven months every two weeks during the eighth month and every week during the ninth month In these examinations particular attention must be paid to the features of incipient heart failure, namely dyspnea, cough bilateral pulmonary rales hepatomegaly unusual edema, and tachycardia Great care must be exercised in the prevention of respiratory infections These may readily precipitate cardiac failure Infections such as the common cold and sore throat must be treated as major events

It is well to prevent unusual and explosive effort on the patient s part particularly in those months of pregnancy when the circulatory burden is greatest Most pregnant cardiacs should have a minimum of ten hours rest at night and two hours rest in mid afternoon Invalidism, however, is not to be encouraged and reasonable muscular activity is beneficial

Excessive weight may be prevented by diets low in calories and a reasonable sodium restriction If the sodium intake is reduced to only 2 Gm a day, weight loss will follow and the tendency to fluid retention will be lessened

Inasmuch as anemia increases heart output, it is to be actively treated with iron and folic acid Because of the degree of hemodilution a complete correction of anemia is unusual (*See* Chapter 25)

Subacute bacterial endocarditis may develop in one per cent of the pregnant patients with rheumatic heart disease As a precaution dental sepsis should be treated promptly with antibiotics, extensive dental repair should be avoided during pregnancy (unless absolutely necessary)

*The Management of Confinement* —The management of confinement is principally a matter for the obstetrician In all good risk patients labor should be allowed to pursue its normal course The second stage of labor may be shortened by a low forceps delivery It is advisable to give penicillin as a prophylactic agent when labor begins

*The Management of the Post Partum Period* —If the patient is not too exhausted by the procedure nursing is permissible and encouraged Since the circulatory changes in pregnancy regress slowly perhaps over a period of from three to six weeks, activities during this time should be as well guarded as they are during the months of pregnancy

*Future Pregnancies* —It is advisable for the cardiac patient to discuss future pregnancies with the physician at an early date Following delivery a full return to the normal physiologic state may take as long as a year or a year and a half If the cardiac status has not deteriorated a second pregnancy should not be ventured before that time has passed At the same time long intervals between pregnancies are inadvisable because the integrity of the

relationship to arterial supply differentiate these lesions from true infarctions of the heart muscle secondary to coronary artery insufficiency In most instances the myocardial bruising by trauma heals without trace However, nonfatal massive necrosis in the wall of the left ventricle following trauma has occasionally led to formation of aneurysm of that chamber

In the experimental animal cardiac traumatism has caused various types of heart block, presumably due to hemorrhagic infiltration of conduction bundle tissue This has seldom been seen in human hearts but hemorrhagic infiltration of the walls of the auricles a condition productive of arrhythmia is common especially in areas of junction with the great vessels Thus hemorrhage around the orifice of the inferior vena cava and spreading into the adjacent auricular structure is frequently noted after crush injury of the lower chest at or near the mid line Another interesting junctional lesion but one without effect on cardiac rhythm is laceration and rupture in the root of the aorta A traumatic dissecting aneurysm of the aorta just above the valve leaflets will occasionally be seen by every coroner s physician

Valvular damage subsequent to nonpenetrating chest trauma is rare Traumatic rupture of an aortic leaflet has apparently occurred in normal hearts such occurrence appears more plausible in leaflets thickened by syphilis Mitral insufficiency following rupture of the chordae tendinae and papillary muscles subsequent to cardiac traumatism has also been reported The incidence of infectious endocarditis, however, mostly of the acute ulcerative type, but also occasionally of the subacute bacterial type following traumatism in distant portions of the body (which presumably has caused local cellulitis and then sepsis), is greater The involved leaflets are generally the site of previous pathology

*Clinical Aspects* —In cardiac traumatism following direct penetrating chest injury, the heart action is rapid the heart sounds are feeble there is occasionally the friction or splash of hemopericardium Frequently the signs of cardiac tamponade are present this if opportunity permits may be verified by fluoroscopy If a coronary artery has been lacerated, electrocardiographic changes may quickly appear They may be due to pericardial reaction to hemopericardium Some or all of these signs may be noted in any case depending on the extent of the traumatism the degree of emergency and the opportunity for examination Where death has not quickly supervened penetrating or lacerating cardiac trauma most commonly results in tamponade in which diastolic filling of the ventricles is hampered by hemopericardium This is evidenced by a small rapid pulse low blood pressure small pulse pressure increasing venous pressure cyanosis and acute congestion of the liver Shock a common accompaniment may add to or confuse the clinical picture

Cardiac trauma following nonpenetrating chest injury presents a marked variation in its clinical aspects, depending on the site of the injury on the chest wall the manner and degree of the applied force the absence or presence of thoracic bone fracture the extent of the accompanying pleural and pulmonary damage and the age and previous health of the patient In patients rendered unconscious by the accident physical signs afford the only clue Rapid feeble heart action especially in the presence of chest injury, is a common sign of cardiac trauma Rapid arrhythmia is striking confirmation in many cases Repeated electrocardiographic examinations show evidence of abnormality and shifting functional status The conscious patient often speaks of pain at the time of the accident or a few hours later It ranges from a dull nonradiating precordial discomfort to typical angina pectoris Palpitation is commonly mentioned Blood spitting and pain on deep breathing indicate at least intrathoracic traumatism and though generally of pleural and pulmonary origin may have a cardiac significance Cyanosis may or may not be present Congestive heart failure with hepatomegaly and leg edema seldom makes an early appearance unless the heart has been previously involved in advanced spontaneous disease

The time factor is important in the clinical picture of nonpenetrating cardiac trauma-

## CARDIAC TRAUMA

BY BENJAMIN A GOULEY, M D
and WILLIAM G LEAMAN, M D

Cardiac trauma is not so uncommon as previously believed As a result of high speed transportation and industrialization, it has become an important medico legal and clinical entity

*Definition* —This chapter deals with cardiac trauma characterized by structural damage within the heart, in the pericardium, and at the junctional areas of entrance and emergence of the great vessels Profound and fatal physiological disturbance of cardiac function following traumatism in other portions of the body is not included

*Etiology* —Cardiac injury may follow a penetrating wound of the chest wall or a blunt injury, the so-called nonpenetrating chest traumatism Occasionally, sudden compressive injury of the abdomen or a fall from a height may produce intracardiac laceration, especially in the thin walls of the atria Penetrating wounds of the heart result most often from a stab with a knife or other sharp pointed weapon Gunshot wound is a common cause of cardiac injury Flying glass or the like as during a bombing may also penetrate the chest and damage the heart And puncture of the heart by broken ribs is sometimes seen in automobile and airplane accidents Compression of the heart following the application of force to the chest in the antero posterior diameter accounts for most nonpenetrating cardiac traumatism

*Pathology* —The right ventricle is the most common site of direct penetrating injury since the greater part of this chamber is presented anteriorly However the right atrium and the left ventricle are also vulnerable, and the coronary arteries and veins may be lacerated, with resulting hemopericardium and tamponade Since objects producing direct injuries are usually contaminated purulent pericarditis is a common complication, generally followed by adhesion

Nonpenetrating injuries may damage the pericardium, the myocardium, or the valves Involvement of the coronary arteries by nonpenetrating injuries of the chest remains a controversial issue Proved cases have not occurred in the experience of the writers except for instances of massive injury, immediately fatal as the result of widespread crush of the heart Some degree of pericardial inflammation is present in every case of cardiac trauma It may remain localized over the site of the application of force, or it may involve a large portion or all of the pericardial surface In contrast to the pericardial reaction to contaminated puncture this type of pericarditis is nonsuppurative it may be hemorrhagic and fibrinous It seldom gives rise to widespread adhesion

The myocardium may be so compressed as to lead to acute rupture of either ventricle or of the right auricle With lesser involvement hemorrhagic softening of the myocardium may develop as a focal lesion at the site of the applied force or as sometimes seen in cases of "steering wheel compression, the opposite ventricular wall may be bruised in contre-coup manner Sometimes though not often, the necrosis traverses the width of the ventricular wall and causes a delayed rupture as long as two weeks after the accident Microscopically, one notes hemorrhagic and edematous infiltration of the myocardium with separation and disorganization of the fibers Sarcolysis of individual fibers and leucocytic infiltration of varied type are seen in cases of severe injury of this kind Abscess does not occur and the typical coagulation necrosis of ischemic infarction seldom if ever, occurs The gross aspect however, of such a lesion sometimes simulates that of myomalacia following coronary thrombosis and this has been noted by various writers The tendency to hemorrhage the vague demarcation and the often peculiar localization without

relationship to arterial supply differentiate these lesions from true infarctions of the heart muscle secondary to coronary artery insufficiency In most instances the myocardial bruising by trauma heals without trace However, nonfatal massive necrosis in the wall of the left ventricle following trauma has occasionally led to formation of aneurysm of that chamber

In the experimental animal cardiac traumatism has caused various types of heart block presumably due to hemorrhagic infiltration of conduction bundle tissue This has seldom been seen in human hearts but hemorrhagic infiltration of the walls of the auricles a condition productive of arrhythmia, is common especially in areas of junction with the great vessels Thus hemorrhage around the orifice of the inferior vena cava and spreading into the adjacent auricular structure is frequently noted after crush injury of the lower chest at or near the mid line Another interesting junctional lesion but one without effect on cardiac rhythm is laceration and rupture in the root of the aorta A traumatic dissecting aneurysm of the aorta just above the valve leaflets will occasionally be seen by every coroner s physician

Valvular damage subsequent to nonpenetrating chest trauma is rare Traumatic rupture of an aortic leaflet has apparently occurred in normal hearts such occurrence appears more plausible in leaflets thickened by syphilis Mitral insufficiency following rupture of the chordae tendinae and papillary muscles subsequent to cardiac traumatism has also been reported The incidence of infectious endocarditis however mostly of the acute ulcerative type but also occasionally of the subacute bacterial type following traumatism in distant portions of the body (which presumably has caused local cellulitis and then sepsis) is greater The involved leaflets are generally the site of previous pathology

*Clinical Aspects* —In cardiac traumatism following direct penetrating chest injury the heart action is rapid the heart sounds are feeble there is occasionally the friction or splash of hemopericardium Frequently the signs of cardiac tamponade are present this if opportunity permits may be verified by fluoroscopy If a coronary artery has been lacerated, electrocardiographic changes may quickly appear They may be due to pericardial reaction to hemopericardium Some or all of these signs may be noted in any case depending on the extent of the traumatism the degree of emergency and the opportunity for examination Where death has not quickly supervened penetrating or lacerating cardiac trauma most commonly results in tamponade in which diastolic filling of the ventricles is hampered by hemopericardium This is evidenced by a small rapid pulse low blood pressure small pulse pressure increasing venous pressure cyanosis and acute congestion of the liver Shock a common accompaniment, may add to or confuse the clinical picture

Cardiac trauma following nonpenetrating chest injury presents a marked variation in its clinical aspects, depending on the site of the injury on the chest wall the manner and degree of the applied force the absence or presence of thoracic bone fracture the extent of the accompanying pleural and pulmonary damage and the age and previous health of the patient In patients rendered unconscious by the accident physical signs afford the only clue Rapid, feeble heart action especially in the presence of chest injury, is a common sign of cardiac trauma Rapid arrhythmia is striking confirmation in many cases Repeated electrocardiographic examinations show evidence of abnormality and shifting functional status The conscious patient often speaks of pain at the time of the accident or a few hours later It ranges from a dull nonradiating precordial discomfort to typical angina pectoris Palpitation is commonly mentioned Blood spitting and pain on deep breathing indicate at least intrathoracic traumatism and though generally of pleural and pulmonary origin may have a cardiac significance Cyanosis may or may not be present Congestive heart failure with hepatomegaly and leg edema seldom makes an early appearance unless the heart has been previously involved in advanced spontaneous disease

The time factor is important in the clinical picture of nonpenetrating cardiac trauma-

tism. Though an occasional victim of such injury shows indefinite signs of cardiac embarrassment only to die suddenly two weeks later of a ruptured ventricle, such signs usually foretell gradual, often rapid, clinical improvement. A transient episode of cardiac traumatism is often revealed only by progressive electrocardiographic *change, the symptomatology disappearing* before the tracing returns to normal. Auricular arrhythmia, either fibrillation or flutter, in patients previously free from cardiac disease, may be the most persistent sign of cardiac traumatism. Most instances, however, of such arrhythmia show a spontaneous return to normal rhythm or at least a satisfactory response to therapy.

Arrhythmia, T-wave changes and evidence of pericarditis constitute the major electrocardiographic changes in cardiac trauma. Auricular fibrillation and auricular extra systoles are frequent developments, and they develop quickly after an accident. If they make their appearance some days afterwards, their connection with cardiac traumatism is doubtful. Heart block receives disproportionate attention in the literature. Its occurrence is extremely rare. Typical infarction patterns are seen in the steering wheel compression cases, in which T-2 and T-3 inversion is a common finding and clearly indicative of massive bruising or necrosis of the left ventricular myocardium posteriorly. Contrariwise a typical pattern of anterior apical infarction is seldom seen; indeed a flattening or moderate inversion of T waves in the direct and unipolar leads is the usual electrocardiographic evidence of anterior traumatization in the left and right ventricles. Where S-T elevation develops in many or all leads a traumatic pericarditis is usually present.

The clinical incidence of traumatic pericarditis in the nonpenetrating type of cardiac trauma is much lower than pathologic findings would indicate. A pericardial friction is described in a few of the case reports, but it should be noted that physical examination is often carried out under difficult circumstances. Massive bloody effusions may follow serious compressive injury. They seldom develop after moderate bruising of the myocardium. As previously noted cardiac tamponade is common in the penetrating type of cardiac injury. Suppurative pericarditis—and, occasionally, a residual chronic, constrictive pericarditis—may follow the tamponade. The clinical signs of the small immobilized heart may thus develop following traumatism. But, in most cases of post-traumatic pericarditis the pericardial lesion gradually resolves itself, partially or completely, the patient thus escaping the dreaded complication of constrictive cardiac failure.

*Diagnosis.*—A direct penetrating injury to the heart can be diagnosed promptly on the basis of case history and examination. The physical signs of pericardial friction, of cardiac compression, and of acute cardiorespiratory insufficiency will complete the evidence afforded by the external wound. There are occasions, however, when the external wound is scarcely visible, as for example in puncture wound by ice pick or hat pin. Also, the physical signs may on occasion be indecisive. Pallor and a rapid heart action or a moderate muffling of the heart sounds may be the only changes noted in a patient who dies an hour later as a result of cardiac tamponade. Generally the dramatic aspect of the traumatism and of the physical signs leads to a rapid and accurate diagnosis.

The diagnosis of nonpenetrating traumatism presents numerous difficulties. Where the patient has been the victim of serious thoracic injury as evidenced by external bruising, broken ribs or hemoptysis the possibility of cardiac traumatism should always be considered. In some instances the examiner's attention is drawn to obvious injuries of the head and extremities and the chest is scarcely examined. If in such cases the electrocardiograph were routinely employed the incidence of cardiac trauma would be much greater than current statistics indicate. A tentative diagnosis of cardiac trauma should be made if the electrocardiographic tracing reveals arrhythmia in the absence of previous heart disease. *If the tracing reveals acute pericarditis* the diagnosis is almost certainly that of a traumatic lesion. Thus in people recently injured, in the acute and subacute phase of traumatic reaction the electrocardiogram is of paramount diagnostic importance. Abnormal patterns that show no or only

slight change in serial study are also important as indicating the absence of acute cardiac trauma. Many people who have chronic coronary artery insufficiency are involved in accidents. Tracings which in cases of chest injury show chronic myocardial damage should repeatedly be confirmed at short intervals. A comparison of such tracings will show whether the patient has escaped cardiac injury. Sometimes a pre-traumatic tracing is available for comparison. The limitations of electrocardiography are not to be forgotten in diagnosing and estimating the extent of cardiac trauma. Hemorrhage, shock, acidosis, traumatic pneumonia, pulmonary embolism, anesthesia, digitalis and morphine may cause electrocardiographic signs that cloud the diagnosis or make it impossible. A review of the entire clinical picture is often necessary.

Severe cardiac traumatism by blunt nonpenetrating injury of the chest wall is always accompanied by traumatic pleurisy or pneumonitis or both. Absence of such injury, as shown by clinical and (especially) x-ray examination of the chest, makes the diagnosis of cardiac trauma unlikely. Rare exceptions to this rule probably occur when small objects strike the precordium, as, for example, in golf ball trauma of the heart.

The absence of rib fracture does not exclude cardiac trauma. Children and young adults may suffer cardiac tamponade following nonpenetrating injury without rib fracture. Conversely, in persons over 50 cardiac traumatism of any clinical significance is always accompanied by such injury. The location of the injury is of diagnostic importance. Anterior and anterolateral rib fracture may be accompanied by heart damage, but chest injury leading to lateral rib fracture seldom causes it, and right sided posterior rib fracture is free from such complication. Fracture of the clavicles is not associated with cardiac trauma, but a broken sternum is particularly dangerous and x-ray identification of it lends strong support to the diagnosis of cardiac traumatism.

The diagnosis of cardiac trauma becomes increasingly difficult with the passage of time following an accident. Objective signs disappear and subjective complaints form the basis of many problems in the differential diagnosis. Aside from the rare complications of constrictive pericarditis and aneurysm of the left ventricle, cardiac trauma tends toward complete or satisfactory recovery in people with previously normal hearts. World War II taught us that the problem of the chronic or delayed aspect of cardiac traumatism with respect to both diagnosis and prognosis revolves around the question of the effect of chest trauma on previous cardiac pathology.

The important question of the effect of overexertion on hearts with coronary insufficiency is excluded as not truly relevant. However, the effect of hemorrhage and shock following extra-cardiac trauma on coronary insufficiency is of direct connection. Serious coronary disease is adversely affected, but the evidence must appear within reasonable time limits. If secondary coronary occlusion develops beyond two or at the most three weeks, then connection with a traumatic episode is most unlikely. This conclusion is based on the current knowledge of delayed myocardial infarction following coronary occlusion.

Nonpenetrating nonfatal chest traumatism does not directly injure the coronary arteries, even those involved in previous disease. The histological study of serial sections in many cases of severe chest traumatism, cases representing all age levels, has failed to reveal coronary artery injury even in the presence of myocardial contusion. Rare exceptions may exist in the "steering wheel-compression" cases in which traumatism to the right coronary artery could be obscured by the massive myocardial contusion of the posterior and adjacent septal walls of the left ventricle. Patients, mostly elderly, with advanced coronary artery insufficiency not infrequently die suddenly after trauma or the sight of an accident. Even where the chest has been more or less traumatized, sudden death by coronary insufficiency is best explained by neurogenic, emotional or possibly hormonal factors. Contusion will heal in a myocardium previously scarred by coronary insufficiency, as will infarction, only the scar of the latter is larger.

It is difficult to evaluate the effect of cardiac traumatism on the myocardial disease

tism Though an occasional victim of such injury shows indefinite signs of cardiac embarrassment, only to die suddenly two weeks later of a ruptured ventricle, such signs usually foretell gradual, often rapid clinical improvement A transient episode of cardiac traumatism is often revealed only by progressive electrocardiographic change, the symptomatology disappearing before the tracing returns to normal Auricular arrhythmia, either fibrillation or flutter, in patients previously free from cardiac disease may be the most persistent sign of cardiac traumatism Most instances, however, of such arrhythmia show a spontaneous return to normal rhythm or at least a satisfactory response to therapy

Arrhythmia, T-wave changes, and evidence of pericarditis constitute the major electrocardiographic changes in cardiac trauma Auricular fibrillation and auricular extra systoles are frequent developments and they develop quickly after an accident If they make their appearance some days afterwards, their connection with cardiac traumatism is doubtful Heart block receives disproportionate attention in the literature Its occurrence is extremely rare Typical infarction patterns are seen in the steering wheel compression cases, in which T-2 and T-3 inversion is a common finding and clearly indicative of massive bruising or necrosis of the left ventricular myocardium posteriorly Contrariwise, a typical pattern of anterior apical infarction is seldom seen indeed a flattening or moderate inversion of T waves in the direct and unipolar leads is the usual electrocardiographic evidence of anterior traumatization in the left and right ventricles Where S-T elevation develops in many or all leads a traumatic pericarditis is usually present

The clinical incidence of traumatic pericarditis in the nonpenetrating type of cardiac trauma is much lower than pathologic findings would indicate A pericardial friction is described in a few of the case reports but it should be noted that physical examination is often carried out under difficult circumstances Massive bloody effusions may follow serious compressive injury They seldom develop after moderate bruising of the myocardium As previously noted cardiac tamponade is common in the penetrating type of cardiac injury Suppurative pericarditis—and, occasionally, a residual, chronic, constrictive pericarditis—may follow the tamponade The clinical signs of the small immobilized heart may thus develop following traumatism But, in most cases of post traumatic pericarditis the pericardial lesion gradually resolves itself partially or completely the patient thus escaping the dreaded complication of constrictive cardiac failure

*Diagnosis* —A direct penetrating injury to the heart can be diagnosed promptly on the basis of case history and examination The physical signs of pericardial friction, of cardiac compression, and of acute cardiorespiratory insufficiency will complete the evidence afforded by the external wound There are occasions, however, when the external wound is scarcely visible as for example in puncture wound by ice pick or hat pin Also, the physical signs may, on occasion be indecisive Pallor and a rapid heart action or a moderate muffling of the heart sounds may be the only changes noted in a patient who dies an hour later as a result of cardiac tamponade Generally the dramatic aspect of the traumatism and of the physical signs leads to a rapid and accurate diagnosis

The diagnosis of nonpenetrating traumatism presents numerous difficulties Where the patient has been the victim of serious thoracic injury as evidenced by external bruising broken ribs or hemoptysis the possibility of cardiac traumatism should always be considered In some instances the examiner's attention is drawn to obvious injuries of the head and extremities and the chest is scarcely examined If in such cases the electrocardiograph were routinely employed the incidence of cardiac trauma would be much greater than current statistics indicate A tentative diagnosis of cardiac trauma should be made if the electrocardiographic tracing reveals arrhythmia in the absence of previous heart disease If the tracing reveals acute pericarditis the diagnosis is almost certainly that of a traumatic lesion Thus in people recently injured in the acute and subacute phase of traumatic reaction the electrocardiogram is of paramount diagnostic importance Abnormal patterns that show no or only

cardium Since a primary tumor of the heart may be very small, few if any cardiac symptoms may be present Metastases to adjacent structures, however, may be numerous and are generally the cause of death Even large primary growths in the heart structure may be asymptomatic Signs and symptoms, if present at all depend largely on the anatomical location of the growth For example a pedunculated tumor mass in the left atrium may give rise to signs suggestive of mitral stenosis Again varying degrees of heart block may be the result of invasion of the auriculo ventricular bundle Under these circumstances the Adams-Stokes syndrome may be present and sudden death is not uncommon The appearance of an unexplained pericardial effusion in a patient of any age should alert the clinician to the possibility of a neoplasm Pressure on a coronary vessel by a tumor growth may produce pain of the anginal type Rupture of a sarcoma of the pericardium into the pleural cavity may occur and is generally followed by a rapidly downhill course It is possible for tumors extending into the heart chambers particularly the left atrium to initiate thrombus formation Subsequent embolization may occur Though rare sudden death may follow blocking of the mitral or tricuspid orifices by large embolic masses of tumor cells Congestive heart failure develops in some patients as a result of either invasion of the myocardium or the compression of the heart with hypodiastolic filling which follows extensive pericardial involvement

The roentgen silhouette often reveals the presence of an unexplained irregularity of the cardiac border In some cases if these are investigated a diagnosis of cardiac neoplasm is possible *ante mortem* A ventricular aneurysm however should always be excluded in older patients when a puzzling shadow of this type is encountered

A variety of changes may occur in the electrocardiogram though the tracing is not diagnostic of the lesion Tall P waves accompany atrial involvement and atrial fibrillation is always a possibility Occasionally the picture of acute myocardial infarction may be simulated by an invading tumor T wave changes consistent with that condition may then appear Rarely bundle branch block and heart block occur

Clinical diagnosis of a cardiac tumor is most difficult and is seldom made Better diagnostic results might be obtained if neoplasms were always suspected in connection with bloody pericardial effusion The fluid obtained by paracentesis should always be carefully examined for tumor cells by one trained in the proper procedure If congestive failure of unknown etiology is present and responds poorly or not at all to the usual therapeutic measures the diagnosis of cardiac tumor should always be considered Unexplained heart block belongs in the same category A positive history of neoplasm, either past or present is valuable additional evidence in arriving at the diagnosis In retarded children who present cardiac enlargement with or without murmurs and other congenital defects neoplasm of the heart should be considered

*Treatment* —Benign neoplasms of the heart have been successfully treated surgically The percentage, however is very small it would be higher if the diagnosis were always considered unusual physical findings carefully evaluated, and complete studies made early

The treatment of secondary growths involving the heart is unfortunately, entirely symptomatic If cardiac tamponade develops paracentesis of the pericardium is necessary Deep roentgen ray therapy may be helpful when dealing with a susceptible type of primary lesion Nitrogen mustard and its allies may be tried

*Prognosis* —Complete cure as the result of surgical excision of a primary cardiac tumor is possible, provided the growth is single and benign If metastatic growths are present when the patient first seeks treatment the outlook is hopeless The nature of the growths and their location are always important factors in formulating the prognosis

or the valvular insufficiency of chronic rheumatic heart disease Almost certainly, cardiac trauma does not initiate the rheumatic process it probably does not reactivate it Patients with mitral stenosis have recovered from cardiac stab wounds without congestive heart failure or recurring rheumatic carditis However, patients with subacute myocarditis have not been involved in cardiac trauma in sufficient number to permit conclusive study of the relationship of these factors to each other Syphilitic heart disease, valvular and myocardial has traditionally been considered vulnerable to cardiac trauma It has long been recognized *per se as a cause of sudden death Patients* with luetic aortitis have shown at autopsy, however, no greater incidence of myocardial bruising than nonluetic patients, and certainly those who have survived serious chest traumatism for weeks or months have shown no increased incidence of myocardial gumma

In general, cardiac trauma tends to heal as well in diseased hearts as in normal hearts The process is longer in the former because *of diminished circulatory efficiency associated* metabolic disease or concomitant trauma of the lungs, which may cause more cardiac insufficiency than myocardial bruising itself Intensification by trauma of pre-existing heart disease is more commonly believed to occur than is warranted by the results of pathologic study and objective clinical evidence Thorough examination of the patient and a searching review of his history including his hospital chart following the cardiac traumatism, will often determine whether the trauma existed in the beginning or cardiac neurosis developed later

*Treatment* —If the patient survives a penetrating wound *of the heart until he* reaches the emergency ward surgery is generally necessary Where hemopericardium has been relieved by a single paracentesis operation may be avoided Where the signs of cardiac tamponade continue and are progressive, surgical treatment cannot be delayed Blood transfusion is helpful and often necessary The liberal and immediate use of antibiotic therapy has reduced both mortality and the late complications of suppurative pericarditis and empyema

In the nonpenetrating compressive heart injury, as a result of which cardiac tamponade may develop more insidiously the need for surgical intervention must be constantly *considered In patients in whom* electrocardiographic changes occur following chest traumatism, all activity should be curtailed for two or three weeks, the patient remaining under the same supervision as is given a case of myocardial infarction Quinidine therapy is most appropriate where cardiac irritability is evident The patient may return to his previous activity only when all suspicious signs disappear and the electrocardiogram has become stabilized

# TUMORS OF THE HEART

By WILLIAM G LEAMAN, M D

Primary or secondary tumor growths of the heart are rare Their cause is unknown Nevertheless, the diagnosis should always be considered in the presence of a heart lesion of unexplained etiology This is particularly true if the patient is of cancer age or has previously had a malignant process in any other part of the body Since the removal of benign or primary cardiac growths is now possible, the outlook for the patient with such a growth is grave but no longer hopeless

*Primary growths of the heart, however,* are less often encountered than metastatic heart growths The benign cardiac tumors include myxoma rhabdomyoma fibroma lipoma and *angioma The malignant* cardiac tumors include round-cell rhabdomyosarcoma epicardial epithelioma, mesothelial sarcoma of the pericardium and other varieties of sarcoma

The left atrium is usually the site of benign growths Primary malignant tumors are more often found in the right atrium the interventricular septum and the peri

and to obtain biopsy material *Bronchography* by utilization of radiopaque material introduced into the bronchus permits a complete survey of the bronchial tree and any existing anomalies, dilatations strictures fistulas, or bronchial occlusions Its use is advocated when there is suspicion of bronchiectasis or of unexplained hemoptysis chronic cough or wheezing exists or chest *x* rays are difficult to interpret It is contraindicated if exudative tuberculosis exists, the patient is debilitated hemoptysis has recently occurred the patient suffers from decreased vital capacity or thyrotoxicosis chronic nephritis or iodine idiosyncrasy exists

Exploratory thoracotomy is a procedure used when other diagnostic measures have been exhausted

*Laboratory Procedures* —(1) One of the most important laboratory procedures in the diagnosis of tuberculosis is examination of sputum Its amount color consistency, odor and content are all of significance Microscopic examination of the sputum may reveal fibers spirals polymorphonuclear leucocytes eosinophiles bronchial casts parasites broncholiths and cancer cells

The sputum is profuse in bronchiectasis and advanced tuberculosis In the former it tends to be three-layered—the top layer frothy white the bottom layer consisting of yellow pus and the middle layer fluid The sputum is frothy and tenacious in asthma rusty in pneumonia pinkish and frothy in passive congestion blood tinged in infarction bronchiectasis and tuberculosis and frankly red in hemorrhage A foul odor is noted in the sputum in bronchiectasis empyema and abscess if bacillus-coli infection is present The sputum in lung gangrene is fetid and contains tissue fragments

The sputum smear may show the presence of the colorless and hexagonal Charcot Leyden crystals of bronchial asthma and bronchitis Dust and metallic particles in the sputum may indicate a pneumoconiosis

(2) Stomach washings may reveal the presence of tubercle bacilli in swallowed sputum Centrifuged specimens smeared on slides for microscopic study or cultured and inoculated into animals have revealed such bacilli in 90 per cent of the cases of tuberculosis with cavitation

(3) The skin tests commonly used are the tuberculin the coccidioidin and the histoplasmin If properly performed these tests are helpful in diagnosis but establish only that infection of the type tested occurred at some previous time and is not necessarily active or even recent With few exceptions a repeated negative reaction rules out the disease in question

(4) Cytologic examination of bronchial washings or sputum may reveal the presence of cancer cells when at least three separate sputa are examined such tests are quite reliable and false positives are few in number Cytologic examination of pleural transudates centrifuged at high speed and the sediment stained with Wright s stain may reveal lymphocytes whereas suppurative exudates show neutrophile leucocytes almost entirely

(5) The erythrocyte-sedimentation test is frequently used as a guide to therapy and prognosis in tuberculosis an accelerated sedimentation rate after prolonged bed rest being a poor prognostic sign Sudden increase in the sedimentation rate may signify impending complications However elevation of the sedimentation rate is not pathognomonic since it is observed in many acute and chronic processes

In diseases of the chest the symptoms are not pathognomonic A symptom seeming to indicate disease of the chest may actually be an expression of involvement of another system of the body while a far advanced lung disease except for possible functional changes may produce no symptoms

*The Clinical Syndrome of Diseases of the Respiratory Tract* —The symptoms most commonly observed in pulmonary disease are cough expectoration dyspnea cyanosis chest pain hemoptysis clubbing of the fingers and toes, fever and polycythemia Any or all of these symptoms may occur in a single case They are helpful to only a small degree in the differential diagnosis of pulmonary infections

*Cough* —Cough is one of the most frequent and most persistent symptoms of pulmonary infections yet it may be slight or entirely

# Diseases of the Respiratory Tract

By J WINTHROP PEABODY M D and J WINTHROP PEABODY Jr M D

## MODERN CONCEPTS OF DISEASES OF THE RESPIRATORY TRACT

Early lesions of the lung even before they produce symptoms are now so readily revealed by *x* ray examination that mass chest surveys of symptomless individuals have become a part of public health measures Diagnosis of pulmonary disease can be made by other procedures in many instances but confirmation of the diagnosis usually demands *x* ray study

The internist should therefore be thoroughly acquainted with the radiologic aspects of thoracic diseases in order to have a clear understanding of the pathologic findings presented and to plan the course of therapy The radiologist must have a knowledge of the basic clinical aspects of pulmonary disease in order properly to evaluate the progress of the disease as depicted in serial films

The respiratory tract is usually considered as having two parts Diseases may affect either the upper or the lower part or both parts The upper respiratory tract consisting of the nose the nasopharynx the mouth and the larynx permits passage of air to the lungs filters out gross material and prevents its entry into the bronchi and by means of the cilia of the mucous membranes, propels to the outside mucus and other secretions collected within the airways The lower respiratory tract, consisting of the trachea bronchi lungs, and pleura has as its particular function oxygenation of the blood and removal of the carbon dioxide

Intensive research in respiratory physiology has brought about a better fundamental knowledge of pulmonary function as a guide to the medical and surgical management of the respiratory tract (*see* page 882)

Advanced knowledge of pulmonary physiology and anatomy, the development of modern methods of anesthesia and improvements in surgical technique now permit thoracotomy and resection of parts of the lung without extreme risk And recently developed diagnostic and therapeutic methods together with the basic measures which have proved effective in the past have served to reduce the mortality rate from diseases of the lung

Roentgenologic diagnosis of pathologic states within the chest are based on interpretation of shadows indicating alterations in the position or the contour of the lung or changes in the pulmonary tissues Fluoroscopy revealing disturbances of the lung's movement position or translucency also is an aid in diagnosis

When the diagnosis has not been established by simple fluoroscopy and radiology tomography (stratigraphy planigraphy laminagraphy) may be employed for localization and definition of deep-seated lesions

*Bronchoscopy* is used in diagnosis and treatment of various intrathoracic diseases It is used to determine the cause of atelectasis and the possible presence of endobronchial inflammation or new growth for the investigation of the cause of chronic cough or wheezing for aspiration of mucous plugs and bronchial secretions for cytologic study

and to obtain biopsy material *Bronchography* by utilization of radiopaque material introduced into the bronchus permits a complete survey of the bronchial tree and any existing anomalies dilatations strictures fistulas or bronchial occlusions Its use is advocated when there is suspicion of bronchiectasis or of unexplained hemoptysis, chronic cough or wheezing exists or chest *x* rays are difficult to interpret It is contraindicated if exudative tuberculosis exists the patient is debilitated hemoptysis has recently occurred the patient suffers from decreased vital capacity or thyrotoxicosis, chronic nephritis or iodine idiosyncrasy exists

Exploratory thoracotomy is a procedure used when other diagnostic measures have been exhausted

*Laboratory Procedures* —(1) One of the most important laboratory procedures in the diagnosis of tuberculosis is examination of sputum Its amount color consistency odor and content are all of significance Microscopic examination of the sputum may reveal fibers spirals polymorphonuclear leucocytes eosinophiles bronchial casts parasites, broncholiths and cancer cells

The sputum is profuse in bronchiectasis and advanced tuberculosis In the former it tends to be three layered—the top layer frothy white the bottom layer consisting of yellow pus and the middle layer fluid The sputum is frothy and tenacious in asthma rusty in pneumonia pinkish and frothy in passive congestion blood tinged in infarction bronchiectasis and tuberculosis and frankly red in hemorrhage A foul odor is noted in the sputum in bronchiectasis empyema and abscess if bacillus-coli infection is present The sputum in lung gangrene is fetid and contains tissue fragments

The sputum smear may show the presence of the colorless and hexagonal Charcot-Leyden crystals of bronchial asthma and bronchitis Dust and metallic particles in the sputum may indicate a pneumoconiosis

(2) Stomach washings may reveal the presence of tubercle bacilli in swallowed sputum Centrifuged specimens smeared on slides for microscopic study or cultured and inoculated into animals have revealed such bacilli in 90 per cent of the cases of tuberculosis with cavitation

(3) The skin tests commonly used are the tuberculin the coccidioidin and the histoplasmin If properly performed these tests are helpful in diagnosis but establish only that infection of the type tested occurred at some previous time and is not necessarily active or even recent With few exceptions a repeated negative reaction rules out the disease in question

(4) Cytologic examination of bronchial washings or sputum may reveal the presence of cancer cells when at least three separate sputa are examined such tests are quite reliable and false positives are few in number Cytologic examination of pleural transudates centrifuged at high speed and the sediment stained with Wright s stain may reveal lymphocytes whereas suppurative exudates show neutrophile leucocytes almost entirely

(5) The erythrocyte sedimentation test is frequently used as a guide to therapy and prognosis in tuberculosis an accelerated sedimentation rate after prolonged bed rest being a poor prognostic sign Sudden increase in the sedimentation rate may signify impending complications However elevation of the sedimentation rate is not pathognomonic since it is observed in many acute and chronic processes

In diseases of the chest the symptoms are not pathognomonic A symptom seeming to indicate disease of the chest may actually be an expression of involvement of another system of the body while a far advanced lung disease except for possible functional changes may produce no symptoms

*The Clinical Syndrome of Diseases of the Respiratory Tract* —The symptoms most commonly observed in pulmonary disease are cough expectoration dyspnea cyanosis chest pain hemoptysis clubbing of the fingers and toes fever and polycythemia Any or all of these symptoms may occur in a single case They are helpful to only a small degree in the differential diagnosis of pulmonary infections

*Cough* —Cough is one of the most frequent and most persistent symptoms of pulmonary infections yet it may be slight or entirely

absent in some of the most serious affections of the lung Cough is normally a protective reflex designed to expel foreign bodies, as well as obstructive accumulations of mucus, from the bronchus but it may also force infective material downward into the lung

The type of cough varies according to the infective process in the pulmonary mucous membranes Chronic coughs accompany pulmonary tuberculosis, chronic bronchitis, heart disease, asthma, emphysema and bronchiogenic carcinoma When an unexplained chronic cough develops between the ages of 40 and 65, a bronchiogenic *carcinoma must be ruled out*

A dry hacking cough is noted in obstruction of the larynx, inflammation of the vocal cords, tracheal inflammation, bronchitis bronchopneumonia, and pleurisy it is paroxysmal in pneumonitis Muffled reverberating cough occurs in emphysema becoming toneless in the senile patient A wheezy or squeaky cough is noted in bronchial obstruction and in allergic diseases A loose throaty cough occurs in tuberculosis bronchiectasis, and abscess of the lung or in suppurative processes A short, deep *painful cough may be indicative of involvement* of the parenchyma and pleura Coughing with gagging and vomiting follows inspiration of a foreign body However, coughing attended by vomiting is often psychogenic and may persist long after the initial infection has subsided

*Expectoration* —When the self-cleansing power of the pulmonary tract proves ineffective, an accumulation of exudate foreign matter and inflammatory products occurs in the lung A short hacking cough is usually enough to expel the material in mild cases

The amount and frequency of expectoration the consistency color and odor of the sputum, its content of cellular bacterial and foreign materials are all of importance in diagnosis

*Dyspnea* —Dyspnea or labored breathing indicating disturbance of the respiratory mechanism occurs in many of the pulmonary diseases but often it indicates cardiac failure as well Dyspnea means that the lungs are unable to meet the demands upon them without effort During violent exercise of course strenuous breathing is due to fatigue not to pathologic weakness Dyspnea may be caused by metabolic disturbances, circulatory diseases, and nervous disorders It is not an early symptom of tuberculosis unless there is considerable or rapid reduction of the lung volume as in massive pleural effusion or spontaneous pneumothorax in which case there is deep stertorous breathing with lengthening of the inspiratory phase In emphysema and in chronic asthma accumulation of stagnant air causes prolonged and labored expiration

*Hoarseness* is a frequent accompaniment of chest diseases, the larynx becoming *secondarily involved either by direct extension* of the infection or by involvement of the recurrent laryngeal nerve A persistent hoarseness, hoarseness that has lasted for several weeks or more without known cause, may be due to syphilis, neoplasm or tuberculosis careful study is required to determine the basic etiology

*Wheezing* results from narrowing of air passages Diffuse wheezing may be caused by asthma or cardiac conditions in which decompensation is present or in cases of left ventricular failure by pulmonary edema *Unilateral wheezing is characteristic of* neoplasm although intrabronchial foreign bodies are an additional consideration

*Cyanosis* —Cyanosis is the dusky bluish hue imparted to the skin by the accumulation of an increased amount of reduced hemoglobin in the circulating capillary blood It has been demonstrated that at least 5 gm of reduced hemoglobin per 100 cc of blood must be present before cyanosis occurs The discoloration is usually best seen in the nailbeds mucous membranes and conjunctival vessels but as the amount of reduced hemoglobin increases the cyanosis becomes evident over the entire skin surface

Any condition interfering with oxygenation of the blood may produce cyanosis Thus it may result from diminished alveolar ventilation due to an obstructed air passage atelectasis or sudden pneumothorax or from a reduced diffusion coefficient through the alveolar membrane due to pulmonary edema or interstitial pulmonary fibrosis In certain instances several factors may contribute to cyanosis For example in lobar

pneumonia the loss of a considerable number of functioning alveoli through consolidation may be combined with rapid shallow respirations enforced by a pleuritic pain to produce a marked cyanosis

Aside from pulmonary sources of cyanosis, there are the added possibilities of the removal of excessive amounts of oxygen in a stagnant bloodstream or of the shunting of large amounts of venous blood into the arterial system as in congential heart disease (For diseases of the circulation producing cyanosis *see* page 762 )

*Note* —Cyanosis due to methomeglobinemia is to be distinguished from cyanosis of pulmonary or *cardiac origin Methemoglobinemic cyanosis may* be primary or congenital hemoglobinemia (This is due to a defect in normal red-cell mechanism to reconvert methemoglobin to hemoglobin The normal ratio is 99 hemoglobin to 1 methemoglobin in congenital cyanosis methemoglobin is kept at a level of about 40 per cent) Secondary methemoglobinemic cyanosis is due to ingestion of nitrates acetophenatidin and acetanilid For detailed discussion *see*

EDITOR

*Chest Pain* —Pain in the chest is neither common nor significant in diagnosis of pulmonary disease but may be the symptom that first attracts the attention of the patient Its commonest causes are pleurisy neuritis fibrositis or it may originate from cardiac and abdominal disease thereby causing considerable confusion in diagnosis It may be present with or without friction rub and varies in intensity according to the degree and rapidity of the stretching of the pleura

Pain in the chest is not a measure of the severity of the pulmonary disease present since it may be absent in cases of severe involvement of the lung—the lungs and visceral pleura have no pain sense whereas the parietal pleura is intensely sensitive Irritation of the diaphragmatic pleura produces a referred pain in the neck and shoulder, where the phrenic nerve originates

*Hemoptysis* —Bloodspitting occurs to some degree in most diseases of the lower respiratory tract but the amount of blood expectorated often has no relation to the severity of the disease Fatal hemorrhage is rare Profuse hemorrhage however may occur in cases of chronic disease with lung cavitation (bronchiectasis, carcinoma, lung abscess and fibroid tuberculosis) The bleeding usually proceeds from a bronchial artery in bronchiectasis and carcinoma and from the pulmonary artery in such ulcerative affections as tuberculosis Mitral stenosis and congestive heart disease when associated with pulmonary infarction, often cause bloodspitting Hemoptysis is rarely associated with shock or severe chest pain, except during vascular crisis

*Clubbing of Fingers and Toes* —Clubbing of the fingers and the toes is often associated with pulmonary diseases The etiology is not understood but the clubbing is generally considered to be due to a disturbance of gas exchange in the capillary circulation of the digits There may also be hypertrophy *of the lower ends of the long bones or chronic* hypertrophic pulmonary osteoarthropathy In cases of lung abscess emphysema and obstruction of the air passages by a foreign body this symptom may occur suddenly It will as rapidly disappear however, when these conditions are cured

*Fever* and *malaise*, nonspecific reactions to infections and to malignancy, are of frequent occurrence in pulmonary disease

*Polycythemia* is frequently observed in *subacute and chronic pulmonary disease* and may be considered a compensatory phenomenon for the purpose of increasing the available amount of oxygen-carrying hemoglobin It is most commonly associated with extensive fibrosis and hypertropic emphysema

Pulmonary arteriovenous aneurysm is a less common cause of polycythemia

## DISEASES OF THE UPPER RESPIRATORY TRACT

By ADRIAN J DELANEY M D

THE upper respiratory tract includes the nose and nasopharynx the mouth and oro-

pharynx and the larynx. An understanding of the anatomic relations and physiologic functions of these structures will help the examiner develop a rational approach to the diagnosis and treatment of the inflammatory and neoplastic lesions encountered in them.

To see these regions adequately, the practitioner must master the use of the head mirror or a headlight with a bright focal beam. Examination of the nasopharynx, the hypopharynx and the larynx with appropriate laryngeal mirrors requires a certain amount of dexterity and considerable practice but the information obtained is worth the effort. The nasopharynx has appropriately been termed "no man's land" because of an almost universal failure to consider it in diseases of the upper respiratory tract. The reasons for this neglect are easily understood when one attempts to examine the postnasal space in an apprehensive gagging patient with a muscular tongue. Reassurance of the patient coupled with gentle firmness on the part of the physician will often be rewarded by an early diagnosis of a malignancy that would otherwise remain in obscurity until far advanced. The simple diagnostic tools of the otolaryngologist are very useful in examining the far recesses of the nose and throat.

## NOSE AND NASOPHARYNX

The nose and nasopharynx function as air conditioners for the lower respiratory tract. The vibrissae of the nasal vestibule help filter out gross foreign particles. The vascular nasal turbinates with their ciliated epithelium and slowly moving mucous blanket warm and moisten the inspired air as it passes to the nasopharynx where it strikes the baffle plate of the pharyngeal tonsils (adenoids) before being shunted downward to the larynx. The paranasal sinuses, most of which can be considered as extensions of primary ethmoid cells, hollow out the facial and cranial bones surrounding the nose. The superior maxilla, frontal, ethmoid, and sphenoid bones are thereby made lighter and less difficult to carry in man's upright position. The air spaces in these bones are considered resonance chambers by some rhinologists. The delicate ciliated epithelium lining these spaces is covered by a thin mucous blanket that is normally swept toward the natural opening of the sinuses in a perpetual house-cleaning effort. Interference with this ciliary activity by inflammatory or allergic changes may transform the resonance chambers into rigid walled cesspools that encourage the growth of anaerobes, defy drainage and lead to chronic osteomyelitis.

Inflammations of the nasal vestibule, in the form of cellulitis or furuncle, are common. The tender, warm, red nasal tip should be treated with great respect because of the ease with which inflammations in this area reach the cavernous sinus. Hot moist compresses gently applied to the inflamed nasal tip and supported by systemic antibiotic and chemotherapeutic treatment, will usually bring about resolution of the process. Surgery is seldom indicated except to lift an obstructing crust from the apex of a pointing abscess. Repeated inflammation of the entrance of the nose may be an indication of an underlying systemic condition (diabetes, anemia, *etc.*)

Acute rhinitis, or rhinosinusitis, as it should be called, is an inflammation of the mucous membrane of the nose and its extensions into the paranasal sinuses and the nasopharynx. If the mucosal and submucosal tissues of the nose alone are involved, a simple rhinitis exists. Spread of the inflammation to the paranasal sinuses is resisted by the mucous blanket and its antibacterial enzymes, but in spite of this protective device the mucous membrane of the sinuses is frequently involved in the inflammation. Extension of the inflammatory process backward into the nasopharynx will produce a nasopharyngitis. From the nasopharynx there may be contiguous involvement of the pharyngeal orifice of the eustachian tubes with progressive inflammation reaching the middle ear and mastoid cells. If the inflammation moves downward from the nasopharynx there may be involvement of the larynx and tracheobronchial mucosa producing laryngitis, bronchitis or bronchopneumonia.

Acute rhinitis is very common. It is especially prevalent in the spring and fall in the temperate zones but it prevails the year round to lesser degree in all countries of the world. This universal occurrence allows the term "common cold" to be given to the condition.

*Etiology.*—The etiology of most cases of acute rhinitis is fairly characteristic. Lower

ing of general body resistance by chilling or wetting is followed by lowering of the temperature of the nasal mucosa with vasoconstriction stasis and anoxemia of this tissue The filterable cold virus initiates the catarrhal inflammation in the epithelium and encourages secondary invasion without symptoms by the pathogenic bacteria that are usually present in the nose and throat under normal conditions These secondary invaders include the hemolytic streptococci pneumococci staphylococci hemophilus influenzae and others

*Pathology* —The pathologic picture of acute rhinitis is one of early ischemia of the mucous membrane of the nose with scanty secretion followed by acute congestion with copious watery discharge Microscopic studies by Hilding revealed early edema of the submucosa followed by infiltration of macrophages and polymorphonuclear cells The epithelial surface sloughs off and disintegrates to form part of the nasal discharge As the submucosal infiltration progresses the secretions become more purulent Reparative processes begin as early as the fifth or sixth day with regeneration of the epithelium to produce a new intact nasal mucosa

*Symptoms* —Clinically there is early general malaise headache muscle aching dryness and a scratchy sensation in the nose and throat followed in several hours by nasal stuffiness some loss of smell watery discharge sneezing lacrimation chilly sensations fatigue and slight temperature elevation The symptoms persist for from four to six days or more and slowly subside The watery discharge may cause excoriations of the nasal vestibules but may also be produced by excessive blowing and wiping of the nose The watery discharge becomes thick and purulent and finally tenacious and dried forming crusts in the nasal cavities as the condition subsides

It should be realized that acute rhinitis may be the introduction to one of the contagious diseases of childhood such as measles pertussis or chickenpox Conservatism in returning the child to school after an attack of acute rhinitis is therefore indicated Intensification of the inflammatory process at any stage or interference with the resolution of that process may lead to complications The chief complications are acute purulent sinusitis and acute otitis media

*Complications* — *Acute sinusitis* occurs during the common cold by entrance into the sinus of secondary invaders usually found in the nose The invasion of the sinus is encouraged by local abnormalities such as deviation of the nasal septum polyps, and hypertrophied nasal turbinates Forceful entry of water into the sinuses in swimming and diving will invite infection in the presence of the common cold The pathologic changes closely resemble those of the nasal mucosa in acute rhinitis The symptoms are those of the common cold at first but as the nasal stuffiness and discharge subsides the purulent sinus discharge appears at the nares and in the postnasal space where it may cause rawness in the nasopharynx and laryngeal irritation with hoarseness and coughing Headache is common fever and malaise occur and there may be tenderness over the maxillary antrum or frontal sinus The treatment of acute purulent sinusitis consists in drainage with an isotonic vasoconstrictor such as neosynephrine or ephedrine in physiologic salt solution relief of pain with analgesics such as the salicylates and codeine and systemic therapy with antibiotics or chemotherapeutic agents as indicated

*Acute otitis media* as a complication of the common cold, usually results from the spreading of inflammation up the eustachian tube and into the middle ear Sneezing forceful blowing of the nose nasal douching swimming and diving may act as inciting agents The pathologic changes in the middle ear may be minimal with congestion and edema of the subepithelial layers and serous discharge or the epithelium may become swollen and the submucosa infiltrated with cells of inflammation leading to pus formation The symptoms are characteristic There is early fulness and pressure in the ear followed by mild sharp pains that increase in severity if the pressure in the middle ear is not relieved by spontaneous perforation or paracentesis Fever varies from 101° F in mild cases to 103 or 104 F in severe purulent involvements Deafness is present to some degree There is usually general malaise headache and anorexia In infants

pharynx and the larynx. An understanding of the anatomic relations and physiologic functions of these structures will help the examiner develop a rational approach to the diagnosis and treatment of the inflammatory and neoplastic lesions encountered in them.

To see these regions adequately, the practitioner must master the use of the head mirror or a headlight with a bright focal beam. Examination of the nasopharynx, the hypopharynx and the larynx with appropriate laryngeal mirrors requires a certain amount of dexterity and considerable practice, but the information obtained is worth the effort. The nasopharynx has appropriately been termed "no man's land" because of an almost universal failure to consider it in diseases of the upper respiratory tract. The reasons for this neglect are easily understood when one attempts to examine the postnasal space in an apprehensive gagging patient with a muscular tongue. Reassurance of the patient coupled with gentle firmness on the part of the physician will often be rewarded by an early diagnosis of a malignancy that would otherwise remain in obscurity until far advanced. The simple diagnostic tools of the otolaryngologist are very useful in examining the far recesses of the nose and throat.

## NOSE AND NASOPHARYNX

The nose and nasopharynx function as air conditioners for the lower respiratory tract. The vibrissae of the nasal vestibule help filter out gross foreign particles. The vascular nasal turbinates with their ciliated epithelium and slowly moving mucous blanket *warm and moisten the inspired air as it* passes to the nasopharynx, where it strikes the baffle plate of the pharyngeal tonsils (adenoids) before being shunted downward to the larynx. The paranasal sinuses, most of which can be considered as extensions of primary ethmoid cells, hollow out the facial and cranial bones surrounding the nose. The superior maxilla, frontal, ethmoid and sphenoid bones are thereby made lighter and less difficult to carry in man's upright position. The air spaces in these bones are considered resonance chambers by some rhinologists. The delicate ciliated epithelium lining these spaces is covered by a thin mucous blanket that is normally swept toward the natural opening of the sinuses in a perpetual house cleaning effort. Interference with this ciliary activity by inflammatory or allergic changes may transform the resonance chambers into rigid walled cesspools that encourage the growth of anaerobes, defy drainage and lead to chronic osteomyelitis.

Inflammations of the nasal vestibule in the form of cellulitis or furuncle, are common. The tender, warm, red nasal tip should be treated with great respect because of the ease with which inflammations in this area reach the cavernous sinus. Hot moist compresses gently applied to the inflamed nasal tip and supported by systemic antibiotic and chemotherapeutic treatment will usually bring about resolution of the process. Surgery is seldom indicated, except to lift an obstructing crust from the apex of a pointing abscess. Repeated inflammation of the entrance of the nose may be an indication of an underlying systemic condition (diabetes, anemia, *etc.*)

Acute rhinitis, or rhinosinusitis, as it should be called, is an inflammation of the mucous membrane of the nose and its extensions into the paranasal sinuses and the nasopharynx. If the mucosal and submucosal tissues of the nose alone are involved a simple rhinitis exists. Spread of the inflammation to the paranasal sinuses is resisted by the mucous blanket and its antibacterial enzymes, but in spite of this protective device the mucous membrane of the sinuses is frequently involved in the inflammation. Extension of the inflammatory process back*ward into the nasopharynx will produce* a nasopharyngitis. From the nasopharynx there may be contiguous involvement of the pharyngeal orifice of the eustachian tubes with progressive inflammation reaching the middle ear and mastoid cells. If the inflammation moves downward from the nasopharynx there may be involvement of the larynx and tracheobronchial mucosa producing laryngitis, bronchitis or bronchopneumonia.

Acute rhinitis is very common. It is especially prevalent in the spring and fall in the temperate zones but it prevails the year round to lesser degree in all countries of the world. This universal occurrence allows the term "common cold" to be given to the condition.

*Etiology.*—The etiology of most cases of acute rhinitis is fairly characteristic. Lower

ing of general body resistance by chilling or wetting is followed by lowering of the temperature of the nasal mucosa with vasoconstriction stasis and anoxemia of this tissue The filterable cold virus initiates the catarrhal inflammation in the epithelium and encourages secondary invasion without symptoms by the pathogenic bacteria that are usually present in the nose and throat under normal conditions These secondary invaders include the hemolytic streptococci pneumococci staphylococci hemophilus influenzae and others

*Pathology*—The pathologic picture of acute rhinitis is one of early ischemia of the mucous membrane of the nose with scanty secretion followed by acute congestion with copious watery discharge Microscopic studies by Hilding revealed early edema of the submucosa followed by infiltration of macrophages and polymorphonuclear cells The epithelial surface sloughs off and disintegrates to form part of the nasal discharge As the submucosal infiltration progresses the secretions become more purulent Reparative processes begin as early as the fifth or sixth day with regeneration of the epithelium to produce a new intact nasal mucosa

*Symptoms*—Clinically there is early general malaise headache muscle aching dryness and a 'scratchy sensation in the nose and throat followed in several hours by nasal stuffiness some loss of smell watery discharge sneezing lacrimation chilly sensations fatigue and slight temperature elevation The symptoms persist for from four to six days or more and slowly subside The watery discharge may cause excoriations of the nasal vestibules but may also be produced by excessive blowing and wiping of the nose The watery discharge becomes thick and purulent and finally tenacious and dried forming crusts in the nasal cavities as the condition subsides

It should be realized that acute rhinitis may be the introduction to one of the contagious diseases of childhood such as measles pertussis or chickenpox Conservatism in returning the child to school after an attack of acute rhinitis is therefore indicated Intensification of the inflammatory process at any stage or interference with the resolution of that process may lead to complications The chief complications are acute purulent sinusitis and acute otitis media

*Complications — Acute sinusitis* occurs during the common cold by entrance into the sinus of secondary invaders usually found in the nose The invasion of the sinus is encouraged by local abnormalities such as deviation of the nasal septum polyps and hypertrophied nasal turbinates Forceful entry of water into the sinuses in swimming and diving will invite infection in the presence of the common cold The pathologic changes closely resemble those of the nasal mucosa in acute rhinitis The symptoms are those of the common cold at first but as the nasal stuffiness and discharge subsides the purulent sinus discharge appears at the nares and in the postnasal space where it may cause rawness in the nasopharynx and laryngeal irritation with hoarseness and coughing Headache is common fever and malaise occur and there may be tenderness over the maxillary antrum or frontal sinus The treatment of acute purulent sinusitis consists in drainage with an isotonic vasoconstrictor, such as neosynephrine or ephedrine in physiologic salt solution relief of pain with analgesics such as the salicylates and codeine and systemic therapy with antibiotics or chemotherapeutic agents as indicated

*Acute otitis media* as a complication of the common cold usually results from the spreading of inflammation up the eustachian tube and into the middle ear Sneezing forceful blowing of the nose nasal douching swimming and diving may act as inciting agents The pathologic changes in the middle ear may be minimal with congestion and edema of the subepithelial layers and serous discharge or the epithelium may become swollen and the submucosa infiltrated with cells of inflammation leading to pus formation The symptoms are characteristic There is early fulness and pressure in the ear followed by mild sharp pains that increase in severity if the pressure in the middle ear is not relieved by spontaneous perforation or paracentesis Fever varies from 101 F in mild cases to 103 or 104° F in severe purulent involvements Deafness is present to some degree There is usually general malaise headache and anorexia In infants

there may be vomiting and convulsions Examination of the ear reveals early injection of the eardrum along the hammer handle and at the periphery Later, the entire drum becomes reddened and injected, with loss of landmarks and normal sheen Bloody discharge or bulging may be seen in the posterior portion Mastoid tenderness is a warning sign of further spread This complication of the common cold demands the use of systemic chemotherapy or antibiotics, local use of heat mild analgesics, and supportive therapy including bed rest Consultation with an otologist should not be delayed if the symptoms and signs are progressive

*Treatment* of acute rhinitis is not specific Early bed rest and isolation of the patient are good advice and help prevent the spread of colds Salicylates alone or combined with codeine or papaverine, will relieve headache and muscular pains A combination of papaverine and codeine, one fourth grain of each, may shorten the course of the cold The drinking of fluids in the form of fruit juices, water, or carbonated beverages should be encouraged, and the diet should be light and easily digested Nasal discomfort may be relieved by a mild vasoconstrictor such as ½ per cent neosynephrine or ephedrine in physiologic salt solution Steam inhalations may give symptomatic relief A mild laxative is indicated if a tendency toward constipation has preceded the onset of the rhinitis The use of antibiotics or chemotherapeutic agents in the treatment of uncomplicated acute rhinitis is not indicated

## MOUTH AND OROPHARYNX

The mouth and oropharynx should be considered together since any inspection of the throat or pharynx must necessarily include the mouth (For a discussion of Diseases of the Oral Cavity *see* Chapter 27 )

### Acute Pharyngitis

Acute catarrhal pharyngitis is a generalized inflammation of the mucous membrane of the pharynx It may be the initial stage of acute rhinitis or sinusitis or of an acute inflammation of the lower respiratory tract Sometimes it occurs with an acute stomatitis

*Etiology*—The etiologic agent is usually the hemolytic streptococci, although staphylococci, pneumococci, streptococcus viridans and influenza and colon bacilli have been inciting or contaminating agents in many cases That a virus is the cause of the condition has not been proved The onset of acute pharyngitis is encouraged by a lowering of the general body resistance by alcoholic excess chilling, constipation or exhaustion from overwork The condition begins with dryness, soreness and burning in the throat, discomfort in swallowing tender enlarged cervical lymphnodes low grade fever, malaise generalized muscle aching and headaches Thick, tenacious secretion is produced in excess and causes much hawking and rasping as the patient tries to expectorate

*Pathology* —The pathologic picture is one of acute congestion of the mucous membrane of the pharynx increased secretion of the mucous glands producing a copious thick saliva and a lymphoid type of cellular infiltration of the epithelial tissues especially around the dilated blood vessels and glands

The diagnosis is based on the characteristic appearance of the bright red congestion of the entire pharynx thick sticky mucus and mild local and general symptoms Acute catarrhal pharyngitis could be the prodromal stage of an acute contagious disease such as measles scarlet fever poliomyelitis or meningitis If the condition fails to respond to simple treatment more serious diseases such as these must be suspected Acute infectious mononucleosis or agranulocytic angina may be confused with simple acute pharyngitis unless blood smears are studied

*Treatment* —The treatment of acute pharyngitis is similar to that recommended for acute rhinitis (*see page 870*) *Local therapy* with warm mild alkaline mouth washes and gargles or irrigations an ice collar for the neck anesthetic throat lozenges and soothing nose drops may be advised *Topical* applications of antiseptics are made useless by the abundant thick secretions that prevent adherence of the medication to the mucous membrane

### Chronic Pharyngitis

Repeated attacks of acute pharyngitis or rhinitis may lead to chronic pharyngitis This condition is characterized by constant or repeated intermittent episodes of dryness and rawness of the throat which is almost constantly sore The pathologic features of importance are thickening of the epithelium dilatation of capillaries perivascular round-cell infiltration of the vessels of the subepithelial tissues and dilated mucous glands

*Signs and Symptoms*—There are abundant, thick tenacious mucous secretions with resultant hawking or coughing and a general feeling of malaise Examination of the throat reveals a dull red velvety thickening of the mucous membrane thick yellowish green adherent secretions and a glazed dull red appearance of the posterior wall of the pharynx

*Treatment*—Treatment of chronic simple pharyngitis is difficult The underlying cause or causes must be searched for and removed if possible Chronic infection in the sinuses or tonsils should be eradicated Systemic conditions such as diabetes nephritis and constipation must be sought for and treated appropriately Chronic abuse of alcohol and tobacco must be forbidden A well rounded diet adequate rest and appropriate open air exercise are basic requirements Full cooperation of the patient is absolutely necessary to effect a satisfactory cure Local therapy with nasal and throat irrigations with saline or mild alkaline solution is sometimes beneficial Stimulating menthol throat lozenges are helpful Removing the secretions and swabbing the inflamed areas with Mandl s iodine solution is good office treatment Systemic chemotherapy and antibiotics are seldom necessary

### Acute Tonsillitis

Acute tonsillitis is a very common affliction frequently undiscovered because the inflammation affects a portion of the pharyngeal lymphoid structures that is not seen in the routine examination Actually there are several lymphoid masses or tonsils in the pharynx In the roof of the pharynx called the nasopharynx the pharyngeal tonsils or *adenoids* are located In childhood the poorly encapsulated masses occupy the mid line of the vault of the pharynx and spread laterally into the recesses of the vault the fossæ of Rosenmuller In this location the lateral extensions of the adenoids may impinge on the pharyngeal openings of the eustachian tubes and interfere with normal exchange of air between the nasopharynx and the middle ear In such cases inflammation of the adenoids may cause repeated attacks of otitis media Deafness of a perception type is commonly caused by hypertrophied adenoid tissue in this region even after adenoidectomy has been performed It is in such cases that the use of radium or roentgen irradiation is advisable to reduce the localized adenoid hypertrophy Below the nasopharynx in the lateral gutters of the pharynx are often found linear masses of lymphoid tissue extending from the eustachian tube openings down behind the posterior pillar of the tonsil and into the hypopharynx where they gradually disappear These masses are seen more commonly following conventional tonsillectomy especially in persons with frequent head colds and postnasal discharge They are so familiar to the otolaryngologist that the name *lateral bands* has been applied to them

In addition to these masses there are two distinct pairs of *tonsils* the faucial and lingual The faucial tonsils have definite boundaries and are located at the vestibule of the pharynx between the anterior and posterior pillars or folds of the fauces The lingual tonsils are situated on the base of the tongue in front of the tip of the epiglottis The faucial tonsils are well known to all physicians and are readily examined The lingual tonsils however are given scant attention by most practitioners because they must be examined by palpation with the finger tip or by drawing the tongue out of the mouth and using a laryngeal mirror This latter maneuver frequently requires time and patience because of the patient s gagging and involuntarily withdrawing the tongue

The four masses of superficial lymphoid tissue in the nasopharynx and the pharynx —the adenoids the lateral bands the faucial tonsils and the lingual tonsils—make up the ring of Waldeyer All may become involved

in inflammation at one time in such conditions as *infectious mononucleosis and diffuse* pharyngeal diphtheria More often, however, one or more of the masses will become hypertrophied or inflamed

*Etiology* —The etiologic agent in acute tonsillitis is *probably a virus in most cases* The hemolytic streptococcus is the offending organism in about 25 per cent of the cases especially when the constitutional symptoms are severe and complications are common *Predisposing factors are chilling of* the body excesses in eating and drinking fatigue and constipation

*Pathology* —The pathologic picture is the same whether found in the adenoids, faucial tonsils, *lingual tonsils or lateral bands* There is a superficial loss of epithelium serous discharge exudation of polymorphonuclear cells from the capillaries edema of the submucosa and congestion of the blood vessels As the process advances there is erosion and ulceration of the submucosa The tonsillar crypts become filled with fibrin desquamated epithelium pus cells and bacteria to produce the yellowish spots on the surface

*Symptoms and Signs* —When the faucial tonsils are involved in acute tonsillitis the symptoms are classical When the adenoids are involved rawness scratching sensations in the postnasal space and nasal speech described as rhinolalia are characteristic When the lymphoid masses in the lateral gutters are involved painful swallowing is especially troublesome When the lingual tonsils are inflamed a sharp stabbing pain in the region of the hyoid bone accompanies swallowing and some dyspnea or hoarseness may be present The patient complains of a lump in the throat

Clinical symptoms of acute tonsillitis begin with a chill *a temperature of 101 to* 104° F headache malaise aching pains in the back and in the extremities painful throat, and anorexia In infants a convulsion may mark the onset of this condition At first the throat is dry then pain on swallowing is noted and, as the inflammation advances there is increasing difficulty in swallowing painful hawking of thick tenacious mucus muffled voice painful enlarged cervical lymphnodes heavily *furred tongue and bad breath*

Examination reveals redness and congestion of the mucous membrane of the pharynx, most marked on the faucial tonsils and the tonsillar pillars The tonsils are swollen *angry red in appearance with yellow or* yellowish white membrane plugging a few or many of the pouting tonsillar crypts The membrane can be removed with relative ease leaving a raw, but not bleeding, base *and often releasing fluid pus from the plugged* crypts If the hemolytic streptococcus is the causative agent there are likely to be intense edema of the tonsillar pillars soft palate and uvula more widespread *membrane formation marked enlargement* and tenderness in the cervical lymph nodes and more severe constitutional symptoms

*Differential Diagnosis* —In the differential diagnosis all conditions characterized by membrane formation in the pharynx must be considered These include diphtheria fusospirochetal pharyngitis thrush infectious mononucleosis and agranulocytosis In children there is always the possibility that an acute sore throat may be an early symptom of scarlet fever measles or meningitis

*Treatment* —Treatment of acute tonsillitis involves bed rest isolation chemotherapy or antibiotic therapy relief of pain and discomfort through the use of analgesics local treatment of the involved tissues and a close watch for impending complications Before any definitive therapy is instituted smears and cultures should be taken to rule out diphtheria and also to identify the causative organism if treatment is not effective It is probably justifiable in severe acute tonsillitis to use full doses of antibiotics as soon as cultures have been taken from the tonsillar membrane even though their effect on a virus is questionable If the secondary invaders present in the pharynx are prevented from disseminating antigen in the circulating blood by antibiotics or chemotherapy the occurrence of such allergic complications as nephritis rheumatic fever or rheumatoid arthritis may be decreased Local therapy in the form of warm saline irrigations soothing medicated lozenges and an ice collar applied to the swollen tender lymphnodes of

the neck will provide some relief An easily digested liquid diet should be offered the first day or two this to be followed by a semi soft diet and then full diet as the dysphagia subsides

### Chronic Tonsillitis

Chronic tonsillitis usually results from repeated attacks of acute tonsillitis the faucial tonsils frequently are primarily involved but the same low-grade chronic inflammation may produce prolonged congestion in any or all of the lymphoid structures that make up Waldeyer s ring In the clinical picture of chronic tonsillitis the tonsil pillars show constant dull redness and congestion accentuated throughout the length of the medial margins The tonsils themselves may be large or small but are usually dull red in color and slightly congested They present several small whitish gray areas of fibrous tissue infiltration resulting from previous acute inflammations Usually one or two enlarged slightly tender lymphnodes occur below the angle of the mandible There is a definite history of repeated attacks of acute tonsillitis often a peritonsillar abscess and frequent head colds There is only one treatment for chronic inflammation of the faucial tonsils—tonsillectomy If the lingual tonsils or the adenoids are chronically inflamed they will present the same sort of appearance as the faucial tonsils and there will be a history *of repeated head colds and sore throat* With adenoid involvement repeated attacks of otitis media with residual deafness can be expected Lingual tonsillitis may cause repeated attacks of simple laryngitis Both conditions will cause excessive amounts of secretions in the pharynx leading to chronic hawking coughing and rasping of the throat Both conditions may be cured by surgical removal of the offending lymphoid masses or by radiation therapy with *x* ray or radium as indicated by the location of the tissue to be treated

It should be remembered that the tonsils and adenoids are frequently invaded by malignant neoplasms especially lymphoepithelioma and lymphosarcoma both of which may cause rapid enlargement of these structures and the regional cervical lymph nodes Such cases should be referred to an expert irradiation therapist as soon as possible

## LARYNX

The larynx is situated just below the pharynx it is in front of the opening of the esophagus and at the top of the tracheobronchial tree At the top the larynx opens widely into the lower pharynx or hypopharynx and at the bottom is continuous with the trachea The larynx may be invaded by inflammatory or neoplastic lesions rather extensively without producing any symptoms It is only when the vocal cords are involved or the glottic airway is encroached upon that the characteristic symptoms of hoarseness and air hunger are elicited Pain is not often complained of unless the perichondrium of one of the laryngeal cartilages is acutely inflamed Inflammation of the larynx especially in infants and young children may progress very rapidly in spite of all treatment so that emergency measures such as tracheotomy or intubation are required early For this reason it is wise to treat these cases in a well-equipped hospital whenever possible Neoplasms of the larynx are fairly common They should be suspected in all cases of hoarseness of over 10 days duration For all practical purposes it is well to assume that there is no such disease as chronic laryngitis until it has been *proved by histopathologic studies of tissues* removed at laryngoscopy by an experienced laryngologist

Acute laryngitis is an acute inflammation of the laryngeal mucosa it is usually widespread in all parts of the larynx It is often associated with the common cold or with an acute exacerbation of a chronic sinusitis The characteristic symptoms are a rough and rasping voice progressing to a rough whisper or even to complete aphonia tickling and dryness in the region of the larynx a dry hacking cough and a slight soreness in the larynx Examination reveals a diffuse redness of the laryngeal mucosa with dilated superficial vessels and thick dry mucous secretion Constitutional symptoms are never more than slight The condition responds

rapidly to voice rest and body rest steam inhalation and avoidance of dusty environments and raw, damp atmospheres The use of finely divided aerosol sprays of Mono-P-*chlorphenol or of gomenol may add to the* patient s comfort

Chronic laryngitis is long continued inflammation of the laryngeal mucous membrane It follows repeated acute attacks, especially when these are secondary to chronic infection in the sinuses or nasopharynx Chronic irritation resulting from tobacco smoke industrial fumes or a dusty environment may predispose to chronic inflammation The voice is rough with a lower pitch than normal vocal fatigue is common There is cough and much hawking to remove sticky secretions On examination the entire mucosa looks a dull velvety red and shows some thickening of the false vocal cords and often of the true vocal cords Treatment is not effective unless the underlying cause is found and eliminated If no cause can be found, malignancy must be suspected

Edema of the larynx may occur as a complication of acute or chronic laryngitis It is seen in phlegmonous inflammations of the floor of the mouth or deep fascial spaces of the neck It may be associated with edema elsewhere in the body as in nephritis or angioneurotic edema The onset is often sudden, causing respiratory embarrassment whispering hoarseness stridulous respiration and panicky asphyxia requiring tracheotomy Mirror examination shows boggy swelling of the entire laryngeal mucosa including the epiglottis and aryepiglottic folds Expert handling is required to avoid asphyxial death If the edema cannot be *reduced by systemic therapy or surgical* drainage of paralaryngeal fascial spaces tracheotomy must be performed

Tuberculous laryngitis is usually secondary to pulmonary tuberculosis but may be primary Slight huskiness of the voice is common in pulmonary tuberculosis, when it becomes marked the larynx should be carefully examined for ulceration, especially if pain is marked If the epiglottis is involved painful deglutition occurs If the cords are ulcerated pain is experienced during phonation The most usual sites of early lesions are the posterior commissure and arytenoid cartilages The mucous membrane is pale in the early stages but later thickens and turns deep red Restricted movements of the vocal cords may be noted If the infection is limited to the intrinsic larynx it usually runs a slow course and is amenable to treatment Involvement of the epiglottis and *arytenoids however, may signify* a rapidly progressive infiltration with extensive ulceration and sloughing off of tissues this offers a poor prognosis Treatment consists of absolute bed rest and voice rest Analgesic sprays help relieve pain Streptomycin given systemically and locally in the form of aerosols, is almost a specific In severe pain, alcohol injection of both *superior laryngeal nerves gives prolonged* relief Quartz ultraviolet light, applied to the larynx by means of special apparatus, is sometimes useful The pulmonary lesions must be brought under control before the laryngeal lesions will become fully quiescent

Syphilis of the larynx is usually seen in the tertiary stage although secondary lesions of the larynx sometimes occur concomitantly with the pharyngeal erythema and the mucous patches of the mouth Primary chancre may be seen on the epiglottis under rare conditions The usual lesion is an infiltration of the entire larynx involving especially the epiglottis and false vocal cords There is a deep red nodular involvement of the mucosa and submucosal tissues this may so progress as to form deep punched out gummatous ulcers unless specific therapy is instituted Serologic tests are usually strongly positive Antiluetic treatment brings prompt improvement

*Cancer of the larynx occurs most fre*quently in the sixth decade in males Epidermoid carcinoma of the true cords is the usual form The earliest warning symptom is hoarseness Pain is often a late symptom *followed by dry cough and hemoptysis* Mirror examination in the early stages may reveal rough thickening of the anterior third of a vocal cord or of the anterior commissure Limitation of movement of the involved cord is a late sign As the disease progresses it spreads locally to involve the entire larynx on the side of origin, and then spreads to the

opposite side Metastatic spread to the cervical lymphnodes is a bad prognostic sign indicating a late stage of the disease The key to the early diagnosis of cancer of the larynx is the maintenance of a high index of suspicion on the part of every practitioner who treats a patient over fifty with hoarseness of 10 days duration All suspicious lesions seen on mirror examination should be biopsied Early lesions confined to one vocal cord are successfully treated surgically in a high percentage of cases with preservation of good phonation Advanced cases require laryngectomy often accompanied by radical dissection of the deep lymphnodes in the neck to relieve pain and allow a chance of cure X ray therapy has its greatest chance of success in highly anaplastic lesions

The larynx is the vestibule of the tracheobronchial tree which consists of the trachea the right and left main bronchi and the secondary and tertiary bronchi The entire laryngotracheobronchial tree can be seen by endoscopy, this method of direct examination has developed rapidly in recent years It is no longer considered a special method of examination which can be performed only by highly trained specialists in large clinics Today endoscopic examination of the larynx trachea and bronchi is second in importance only to $x$ ray examination of the lung in the study of pulmonary disease The interpretation of $x$ ray findings is frequently made with much greater accuracy after the endoscopic examination has been reported The exact localization of isolated lesions of the lungs is made possible by supplementing roentgen visualization with bronchoscopic studies

*Endoscopic Examination of the Tracheobronchial Tree* —In the hands of an experienced manipulator bronchoscopy is neither difficult nor dangerous Usually it is performed under local anesthesia following premedication with morphine and cocaine Sedation is sometimes required to ensure adequate relaxation Hospitalization is unnecessary for most patients since the procedure seldom entails collapse or shock and never produces trauma unless it is unduly protracted or improperly executed

There are certain affections of the respiratory tract for which the endobronchial method seems particularly well adapted for nonsurgical diagnosis and treatment They are chiefly, atelectasis resulting from thick pulmonary secretions bronchiectasis bronchial stenosis, asthma pulmonary abscess malignancy of the lungs, persistent hemoptysis of obscure origin and tuberculosis Each of these conditions of the chest will be considered elsewhere

Pneumonography with bismuth subcarbonate or with a radiopaque substance in oil represents a valuable adjunct to bronchoscopy for the exploration of the tracheobronchial tree in certain instances The instillation of an oily solution may be effected by bronchoscopy, and bronchoscopic pneumonography may be practiced on a fluoroscopic table with the bronchoscope left in position while roentgenograms and fluoroscopic observations are completed Or the opaque medium may be introduced by a laryngeal cannula or catheter The iodized oil may be removed by aspiration through the bronchoscope Cough and postural drainage should be induced immediately following the conclusion of the study Patients should be cautioned not to swallow expectorations which may contain oil

The use of bronchography is limited to lesions not otherwise apparent radiographically hence to those which affect the lumen of the bronchus by obstruction stenosis or dilation Bronchography is principally indicated in (1) bronchiectasis, (2) the differentiation of lesions of the pleural cavity from those of the pulmonary parenchyma (3) the study of the effect of therapeutic procedures and (4) the localization of the trachea and the bronchi for the purpose of the differentiation of lesions of the mediastinum and pericardium

rapidly to voice rest and body rest steam inhalation and avoidance of dusty environments and raw damp atmospheres The use of finely divided aerosol sprays of Mono-P chlorphenol or of gomenol may add to the patient's comfort

Chronic laryngitis is long continued *inflammation of the laryngeal mucous membrane* It follows repeated acute attacks especially when these are secondary to chronic infection in the sinuses or nasopharynx Chronic irritation resulting from tobacco smoke industrial fumes or a dusty environment may predispose to chronic inflammation The voice is rough with a lower pitch than normal Vocal fatigue is common There is cough and much hawking to remove sticky secretions On examination the entire mucosa looks a dull velvety red and shows some thickening of the false vocal cords and often of the true vocal cords Treatment is not effective unless the underlying cause is found and eliminated If no cause can be found malignancy must be suspected

Edema of the larynx may occur as a complication of acute or chronic laryngitis It is seen in phlegmonous inflammations of the floor of the mouth or deep fascial spaces of the neck It may be associated with edema elsewhere in the body as in nephritis or angioneurotic edema The onset is often sudden, causing respiratory embarrassment whispering hoarseness stridulous respiration, and panicky asphyxia requiring tracheotomy Mirror examination shows boggy swelling of the entire laryngeal mucosa including the epiglottis and aryepiglottic folds Expert handling is required to avoid asphyxial death If the edema cannot be reduced by systemic therapy or surgical drainage of paralaryngeal fascial spaces tracheotomy must be performed

Tuberculous laryngitis is usually secondary to pulmonary tuberculosis but may be primary Slight huskiness of the voice is common in pulmonary tuberculosis when it becomes marked the larynx should be carefully examined for ulceration, especially if pain is marked If the epiglottis is involved painful deglutition occurs If the cords are ulcerated pain is experienced during phonation The most usual sites of early lesions are the posterior commissure and arytenoid cartilages The mucous membrane is pale in the early stages but later thickens and turns deep red Restricted movements of the vocal cords may be noted If the infection is limited to the intrinsic larynx it usually runs a slow course and is amenable to treatment *Involvement of the epiglottis* and arytenoids however, may signify a rapidly progressive infiltration with extensive ulceration and sloughing off of tissues this offers a poor prognosis Treatment consists of absolute bed rest and voice rest Analgesic sprays help relieve pain Streptomycin given systemically and locally in the form of aerosols is almost a specific In severe pain, alcohol injection of both superior laryngeal nerves gives prolonged relief Quartz ultraviolet light, applied to the larynx by means of special apparatus, is sometimes useful The pulmonary lesions must be brought under control before the laryngeal lesions will become fully quiescent

Syphilis of the larynx is usually seen in the tertiary stage although secondary lesions of the larynx sometimes occur concomitantly with the pharyngeal erythema and the mucous patches of the mouth Primary chancre may be seen on the epiglottis under rare conditions The usual lesion is an infiltration of the entire larynx, involving especially the epiglottis and false vocal cords There is a deep red nodular involvement of the mucosa and submucosal tissues, this may so progress as to form deep punched-out gummatous ulcers unless specific therapy is instituted Serologic tests are usually strongly positive Antiluetic treatment brings prompt improvement

Cancer of the larynx occurs most frequently in the sixth decade in males Epidermoid carcinoma of the true cords is the usual form The earliest warning symptom is hoarseness Pain is often a late symptom followed by dry cough and hemoptysis Mirror examination in the early stages may reveal rough thickening of the anterior third of a vocal cord or of the anterior commissure Limitation of movement of the involved cord is a late sign As the disease progresses it spreads locally to involve the entire larynx on the side of origin and then spreads to the

opposite side Metastatic spread to the cervical lymphnodes is a bad prognostic sign indicating a late stage of the disease The key to the early diagnosis of cancer of the larynx is the maintenance of a high index of suspicion on the part of every practitioner who treats a patient over fifty with hoarseness of 10 days duration All suspicious lesions seen on mirror examination should be biopsied Early lesions confined to one vocal cord are successfully treated surgically in a high percentage of cases with preservation of good phonation Advanced cases require laryngectomy, often accompanied by radical dissection of the deep lymphnodes in the neck to relieve pain and allow a chance of cure X-ray therapy has its greatest chance of success in highly anaplastic lesions

The larynx is the vestibule of the tracheobronchial tree which consists of the trachea the right and left main bronchi and the secondary and tertiary bronchi The entire laryngotracheobronchial tree can be seen by endoscopy this method of direct examination has developed rapidly in recent years It is no longer considered a special method of examination which can be performed only by highly trained specialists in large clinics Today endoscopic examination of the larynx trachea and bronchi is second in importance only to $x$ ray examination of the lung in the study of pulmonary disease The interpretation of $x$ ray findings is frequently made with much greater accuracy after the endoscopic examination has been reported The exact localization of isolated lesions of the lungs is made possible by supplementing roentgen visualization with bronchoscopic studies

*Endoscopic Examination of the Tracheobronchial Tree* —In the hands of an experienced manipulator bronchoscopy is neither difficult nor dangerous Usually it is performed under local anesthesia following premedication with morphine and cocaine Sedation is sometimes required to ensure adequate relaxation Hospitalization is unnecessary for most patients since the procedure seldom entails collapse or shock and never produces trauma unless it is unduly protracted or improperly executed

There are certain affections of the respiratory tract for which the endobronchial method seems particularly well adapted for nonsurgical diagnosis and treatment They are chiefly, atelectasis resulting from thick pulmonary secretions bronchiectasis bronchial stenosis asthma pulmonary abscess malignancy of the lungs persistent hemoptysis of obscure origin and tuberculosis Each of these conditions of the chest will be considered elsewhere

Pneumonography with bismuth subcarbonate or with a radiopaque substance in oil represents a valuable adjunct to bronchoscopy for the exploration of the tracheobronchial tree in certain instances The instillation of an oily solution may be effected by bronchoscopy and bronchoscopic pneumonography may be practiced on a fluoroscopic table, with the bronchoscope left in position while roentgenograms and fluoroscopic observations are completed Or the opaque medium may be introduced by a laryngeal cannula or catheter The iodized oil may be removed by aspiration through the bronchoscope Cough and postural drainage should be induced immediately following the conclusion of the study Patients should be cautioned not to swallow expectorations which may contain oil

The use of bronchography is limited to lesions not otherwise apparent radiographically hence to those which affect the lumen of the bronchus by obstruction stenosis or dilation Bronchography is principally indicated in (1) bronchiectasis (2) the differentiation of lesions of the pleural cavity from those of the pulmonary parenchyma (3) the study of the effect of therapeutic procedures and (4) the localization of the trachea and the bronchi for the purpose of the differentiation of lesions of the mediastinum and pericardium

## DISEASES OF THE BRONCHI

By J WINTHROP PEABODY M D and J WINTHROP PEABODY JR M D

### ACUTE BRONCHITIS

*Definition and Etiology* —Acute bronchitis or tracheobronchitis, is a catarrhal inflammation of the bronchi Usually it also involves the trachea Though it may be a primary inflammation it commonly results from the spreading of an infection from the upper respiratory tract into the trachea and bronchi It may follow a neglected cold acute rhinitis sinusitis, tonsillitis or pharyngitis Not infrequently it develops as a direct result of diphtheria trichinosis coccidioidomycosis, or irritating gases The contributing factors are often exposure to cold or dampness chilling, fatigue and malnutrition Bronchitis is usually a mild disease unless accompanying a more serious affection such as grippe influenza, measles whooping cough allergic diseases or virus pneumonia The very young the debilitated and the aged are particularly liable to the disease and in these it may become serious

*Clinical Features* —The earliest symptoms of acute bronchitis are a feeling of malaise and tightness or pain in the chest attended by a dry distressing cough Expectoration of mucus brings some relief The cough loosens and the mild fever subsides in a week or ten days If the case is more severe the breathing is asthmatic the cough loud and barking and symptoms may last for several weeks Bronchopneumonia often follows

Physical examination may reveal no abnormal physical signs over the chest if only the trachea and the large bronchi are involved Usually expiration is prolonged with dry wheezing rhonchi are heard as the mucous membranes of the medium sized and smaller bronchi become inflamed and swollen Moist rales are heard as the secretion increases and the expiratory murmur is prolonged as the air passages become partly clogged with mucus As the smaller ramifications become involved high pitched tubular breathing may be noted over the collapsed areas of the lung The tracheal and bronchial membranes are red and swollen and as the disease progresses become velvety in texture The ciliated epithelium is damaged The membranes return to normal with recovery In the uncomplicated case fluoroscopic and radiographic examination are negative

*Differential Diagnosis* —It is necessary to establish whether the acute bronchitis is the sole condition present or is a local manifestation of another disease In children, foreign bodies enlarged mediastinal lymphnodes whooping cough and measles must be ruled out Tuberculosis should be ruled out by radiologic studies and bronchiectasis by bronchographic examination when cough fever and malaise persist Pneumonia is to be suspected when the temperature and the pulse and respiratory rates are elevated

*Treatment* —Prophylactic measures such as avoidance of exposure prevention of contact with known cases of bronchitis and isolation of the patient are important Treatment involves bed rest warm air a bland diet high intake of fluids and keeping the bowels open Small doses of sedatives expectorants and codeine mustard poultices and steam inhalations bring relief especially when the cough is paroxysmal and irritating If there is an associated asthma difficult breathing may be relieved by administration of adrenalin or ephedrin The treatment of the infection should continue even into the convalescent period to prevent development of bronchopneumonia The sulfonamides and penicillin have been found ineffective but good results have been reported in some cases from use of aureomycin Usually antibiotics are not indicated

*Prognosis* —If the bronchitis is associated with a concurrent upper respiratory tract infection the symptoms become more serious and may abate and recur from time to time Mucous plugs may lead to occlusion of the bronchi and collapse of the lung Repeated

attacks of acute bronchitis rarely cause chronic bronchitis

*Acute Laryngotracheobronchitis* —Acute laryngotracheobronchitis occurs most often in children The onset is sudden with inflammation of the membranes severe cough, dyspnea and cyanosis A thick tenacious exudate later appears this becomes gummy and purulent obstructs the bronchial tree and causes atelectasis Distention of the alveoli may lead to mediastinal emphysema and pneumothorax Bacteriologic study will distinguish the disease from laryngeal diphtheria and laryngismus stridulus The clinical picture may be confused with that of bronchopneumonia Tracheotomy or bronchoscopy may be required to relieve the respiratory embarrassment and remove the crusty exudates Oxygen therapy and antibiotic treatment (parenterally and by aerosols) should be employed Morphine is contraindicated Unless prompt and adequate therapy is administered the prognosis is grave

*Ulcerative Tracheobronchitis* —Ulcerative tracheobronchitis which often follows pulmonary abscess sarcoidosis and fungous infections is attended by a persistent cough with blood tinged expectoration and some fever The diagnosis is dependent upon bronchoscopic evidence of ulceration and a history of one of the etiologic diseases Treatment is dependent upon the causative agent

## Chronic Bronchitis

*Definition* —Chronic bronchitis may be defined as prolonged inflammation of the mucous membranes of the bronchi their divisions and subdivisions with a tendency to exacerbation after periods of quiescence The majority of the sufferers are in the late decades of life They have persistent cough during the winter or frequent colds that defy treatment

*Etiology* —Predisposing factors are as follows (1) Lowered resistance Resistance is lowered by chills exposure to dampness fatigue undernourishment debility from recent disease or such local factors as mouth breathing excessive smoking and continued exposure to dusts and fumes (2) Cardiac insufficiency This causes poor oxygenation of the blood and so reduces ciliary defense efficiency (3) Maldevelopment of the chest (4) Chronic pulmonary diseases such as tuberculosis silicosis *etc* (5) Age (6) The microorganisms responsible for chronic bronchitis are (1) fungi and such specific bacteria as tubercle bacilli and (2) the microorganisms usually found in the respiratory tract

*Pathology* —Chronic bronchitis may be hypertrophic or atrophic In the hypertrophic stage hypertrophy of the bronchial wall and thickening of the mucous membrane are noted The mucous secretion is more copious than in acute bronchitis and may be mucoid mucopurulent or purulent In the milder form of the disease the mucosa is chiefly involved but as the bronchitis progresses the deeper layers and peribronchial areas are affected with thickening of the bronchial fibrous tissues and the interstitial septa If the weakened wall yields to pressure bronchiectasis develops

In the atrophic stage gradual disappearance of the bronchial mucous glands and bronchial elastic and muscular tissue is noted

*Symptoms* —The symptoms of chronic bronchitis differ from those of acute bronchitis in degree and duration Cough is the principal symptom A persistent cough is the rule It is usually worse in the morning and is always worse in cold or changeable weather The sputum varies in amount It may be tenacious and scanty so that it is dislodged with difficulty, or copious and semipurulent Sputum streaked with blood is rare unless there is an associated bronchiectasis Dyspnea a frequent symptom increases with the duration of the disease and when severe usually indicates associated cardiac failure or pulmonary fibrosis and emphysema Chest pain is rare

*Signs* —The signs of chronic bronchitis vary depending on the infective agent and on whether the bronchitis is wet or dry In the dry type lung resonance is generally normal dry rhonchi may be heard throughout the chest In the wet type moist rales are noted During acute attacks fever may or may not be present and there is an increase in sputum rales and rhonchi However an afebrile course is not unusual Cyan

osis, when present indicates underlying serious cardiac or pulmonary disease

In asthmatic bronchitis, high pitched musical râles at the end of expiration are noted

*Diagnosis* —The diagnosis of chronic bronchitis is based on the history signs, symptoms, and determination of the underlying cause If the patient has had a chronic productive cough for years without evident impairment of general health and examination fails to reveal evidence of any specific disease in which chronic cough is a predominant feature the diagnosis is established

The sinuses should always be investigated for a causative focus of infection Other foci should be sought in the lung (bronchiectasis cystic disease abscess or cancer) Examination of the sputum may reveal the presence of various organisms such as micrococcus catarrhalis pneumococci streptococci both hemolytic and nonhemolytic, streptococcus viridans Friedländer's bacilli and staphylococci

Roentgen examination is unrevealing in early cases but in patients with recurrent attacks over a period of years striations due to linear fibrosis may be observed in the lungs

*Treatment* —Therapy consists largely in keeping the patient away from unfavorable environments If the patient can afford to reside in a dry locality not subject to abrupt changes in temperature or to excessive cold he may live in considerable comfort The underlying cause of the bronchitis must first be found, of course and eliminated insofar as possible The treatment is entirely medical and is prophylactic and symptomatic The patient should be protected against temperature changes should stay indoors during inclement weather, should wear warm clothing, and above all should be protected against infectious diseases His general resistance should be improved by high caloric high vitamin diet and a reduction in use of alcohol and tobacco A slowing down of pace, with restful days and nights is desirable especially for the older patients

Drugs are administered for relief of symptoms The troublesome cough may be relieved by use of expectorants to liquefy the sputum Potassium or sodium iodide are widely recommended If the *cough* is exhausting small doses of codeine may be necessary Cough should not be controlled however to the extent that the cough reflex is so repressed as to prevent necessary expectoration Postural drainage should be practiced when the raising of sputum proves troublesome Ephedrine which is particularly helpful in bronchospasm, may prove toxic in the aged Other *bronchodilators*, such as orthoxine hydrochloride given orally and isuprel, sublingually, have been found beneficial

Vaccine therapy has proved disappointing Penicillin aerosolization has proved to be a valuable adjunct Deep inhalation of 100 000 units of penicillin dissolved in 3 cc of physiological saline or 1 1000 aqueous solution of zephyran, every 6 to 8 hours for approximately 10 days often results in symptomatic improvement In asthmatic bronchitis nebulization solutions are helpful Richards Barach and Cromwell recommend a mixture of vaponefrin (1-to-100 epinephrine) with or without 1 per cent neosynephrine, in a nebulizer and a flow of from 1000 to 6000 cc of oxygen per minute passed through it from a pressure tank Use of aerosol antibiotic therapy in treatment of chronic bronchitis may produce striking palliative results and occasionally, lasting cures

*Prognosis* —Prognosis depends on control of the underlying disease maintenance of general good health and prevention measures If the patient must remain in an unfavorable environment the prognosis is not good If he is economically able to live in a temperate dry climate he may live in fair comfort for years

## Rare Forms of Bronchitis

*Fibrinous bronchitis* (plastic bronchitis) is an uncommon form of the disease in which tough fibrinous casts formed in the bronchi are ultimately coughed up It may be acute or chronic and may last for years It may be a primary infection or one associated with pulmonary tuberculosis or asthma In its acute form fever pain in the chest cough and dyspnea may occur Expectoration of the casts results in disappearance of symp-

toms Expectorants and supportive measures provide the best therapy

*Bronchiolitis fibrosa obliterans* results from inhalation of irritating gases the symptoms are cough dyspnea and cyanosis The bronchioles are obliterated by obstructive epithelial cells and overgrowth of connective tissue Sedation and continuous oxygen administration constitute treatment

*Spirochaetal bronchitis* is a hemorrhagic bronchitis characterized by the presence of spirochetes in the sputum The symptoms are cough mucopurulent sputum occasional hemoptysis and fever It is a disease rarely noted in this country except in those who have visited the Orient and may be mistaken for pulmonary tuberculosis It can be diagnosed only on sputum examination Arsenic is considered specific for this disease and arsphenamine or mapharsen is usually employed

## Bronchiectasis

*Definition* —Bronchiectasis is a chronic disease characterized by dilatation of the bronchi or bronchioles with pathologic changes in the bronchial walls and adjoining tissues It is due to an inflammatory process and is generally associated with chronic broncho-pulmonary suppuration The patient may long be unaware of its presence or may have symptoms so severe as to be a lifelong invalid or semi invalid The disease is often diagnosed as chronic bronchitis unresolved pneumonia pulmonary abscess pneumonitis or tuberculosis

*Etiology* —Bronchiectasis may be congenital or acquired Congenital bronchiectasis is uncommon It may be associated with situs inversus cystic fibrosis of the pancreas or other congenital anomalies Most cases of bronchiectasis are acquired

The etiology of acquired bronchiectasis remains controversial The principal theory is that mechanical dilatation of the bronchi is followed by weakening of the bronchial walls and failure of adequate drainage with resultant infection of the bronchi Pathologic changes in the bronchial tree are thus brought about by retention of the exudate with further obstruction and infection Bronchial dilatation therefore is not the sole cause of bronchiectasis It is only when such dilatation is accompanied by inadequate drainage facilities and formation of a plug of normal secretions and exudates that bronchial infection and its symptoms are manifested The initial cause of the disease may be the presence of foreign bodies broncholiths bronchopleural fistulas pneumoconiosis enlarged lymphnodes and tuberculous fibrosis Although broncho-pneumonia is considered a precursor of bronchiectasis virus pneumonia is not believed to be an etiologic agent although cases of "psuedo-bronchiectasis" temporary bronchial dilatation have been described in virus pneumonia Infectious diseases such as measles or whooping cough may cause a bronchiectasis Thus any bronchial infection of infancy or childhood may be followed by atelectasis, pneumonitis bronchitis, and finally, bronchiectasis

Sinusitis may precede accompany or follow bronchiectasis but few believe that bronchiectasis is secondary to paranasal sinus infection

Bronchiectasis secondary to tuberculosis is a relatively frequent pathologic finding and is often unrecognized It results from a combination of bronchial and pulmonary factors Tuberculous lesions of the bronchi with associated peribronchial obstruction produce interference with pulmonary ventilation and drainage with resultant retention and stagnation of secretions Chronic pulmonary fibrosis produces loss of elastic tissue and reduction of lung volume Another factor often unappreciated is the effect of tuberculous caseous pneumonia or bronchopneumonia which by decreasing aerated parenchyma and distensibility lowers intrathoracic pressure and exerts traction on the bronchial wall producing ectasia

*Pathology* —The essential process in bronchiectasis has been described as an ulcerative lesion in the bronchi with destruction of the epithelium muscle and elastic fibers of the bronchi and frequent extension of the destructive process into the surrounding tissues of the lung This process is furthered by stenosis of the bronchus a stenosis causing retention of infective secretions and weakening of the elastic tissues resulting in dilatation of the bronchial walls Two main types

osis, when present, indicates underlying serious cardiac or pulmonary disease

In asthmatic bronchitis, high pitched musical rales at the end of expiration are noted

*Diagnosis* — The diagnosis of chronic bronchitis is based on the history, signs symptoms and determination of the underlying cause If the patient has had a chronic productive cough for years without evident impairment of general health and examination fails to reveal evidence of any specific disease in which chronic cough is a predominant feature the diagnosis is established

The sinuses should always be investigated for a causative focus of infection Other foci should be sought in the lung (bronchiectasis cystic disease abscess or cancer) Examination of the sputum may reveal the presence of various organisms such as micrococcus catarrhalis pneumococci streptococci both hemolytic and nonhemolytic streptococcus viridans Friedlander's bacilli and staphylococci

Roentgen examination is unrevealing in early cases but in patients with recurrent attacks over a period of years striations due to lineal fibrosis may be observed in the lungs

*Treatment* —Therapy consists largely in keeping the patient away from unfavorable environments If the patient can afford to reside in a dry locality not subject to abrupt changes in temperature or to excessive cold he may live in considerable comfort The underlying cause of the bronchitis must first be found of course and eliminated insofar as possible The treatment is entirely medical, and is prophylactic and symptomatic The patient should be protected against temperature changes should stay indoors during inclement weather should wear warm clothing and above all should be protected against infectious diseases His general resistance should be improved by high caloric high vitamin diet and a reduction in use of alcohol and tobacco A slowing down of pace with restful days and nights is desirable especially for the older patients

Drugs are administered for relief of symptoms The troublesome cough may be relieved by use of expectorants to liquefy the sputum Potassium or sodium iodide are widely recommended If the cough is exhausting small doses of codeine may be necessary Cough should not be controlled however to the extent that the cough reflex is so repressed as to prevent necessary expectoration Postural drainage should be practiced when the raising of sputum proves troublesome Ephedrine, which is particularly helpful in bronchospasm, may prove toxic in the aged Other bronchodilators such as orthoxine hydrochloride given orally and isuprel, sublingually, have been found beneficial

Vaccine therapy has proved disappointing Penicillin aerosolization has proved to be a valuable adjunct Deep inhalation of 100 000 units of penicillin dissolved in 3 cc of physiological saline or 1 1000 aqueous solution of zephyran, every 6 to 8 hours for approximately 10 days often results in symptomatic improvement In asthmatic bronchitis nebulization solutions are helpful Richard Barach and Cromwell recommend a mixture of vaponefrin (1-to-100 epinephrine) with or without 1 per cent neosynephrine in a nebulizer and a flow of from 4000 to 6000 cc of oxygen per minute passed through it from a pressure tank Use of aerosol antibiotic therapy in treatment of chronic bronchitis may produce striking palliative results and occasionally, lasting cures

*Prognosis* —Prognosis depends on control of the underlying disease, maintenance of general good health and prevention measures If the patient must remain in an unfavorable environment the prognosis is not good If he is economically able to live in a temperate dry climate he may live in fair comfort for years

## Rare Forms of Bronchitis

*Fibrinous bronchitis* (plastic bronchitis) is an uncommon form of the disease in which tough fibrinous casts formed in the bronchi are ultimately coughed up It may be acute or chronic and may last for years It may be a primary infection or one associated with pulmonary tuberculosis or asthma In its acute form fever pain in the chest cough and dyspnea may occur Expectoration of the casts results in disappearance of symp-

toms. Expectorants and supportive measures provide the best therapy.

*Bronchiolitis fibrosa obliterans* results from inhalation of irritating gases, the symptoms are cough, dyspnea and cyanosis. The bronchioles are obliterated by obstructive epithelial cells and overgrowth of connective tissue. Sedation and continuous oxygen administration constitute treatment.

*Spirochaetal bronchitis* is a hemorrhagic bronchitis characterized by the presence of spirochetes in the sputum. The symptoms are cough, mucopurulent sputum, occasional hemoptysis and fever. It is a disease rarely noted in this country except in those who have visited the Orient, and may be mistaken for pulmonary tuberculosis. It can be diagnosed only on sputum examination. Arsenic is considered specific for this disease, and arsphenamine or mapharsen is usually employed.

## Bronchiectasis

*Definition.*—Bronchiectasis is a chronic disease characterized by dilatation of the bronchi or bronchioles with pathologic changes in the bronchial walls and adjoining tissues. It is due to an inflammatory process and is generally associated with chronic broncho-pulmonary suppuration. The patient may long be unaware of its presence or may have symptoms so severe as to be a lifelong invalid or semi-invalid. The disease is often diagnosed as chronic bronchitis, unresolved pneumonia, pulmonary abscess, pneumonitis or tuberculosis.

*Etiology.*—Bronchiectasis may be congenital or acquired. Congenital bronchiectasis is uncommon. It may be associated with situs inversus, cystic fibrosis of the pancreas or other congenital anomalies. Most cases of bronchiectasis are acquired.

The etiology of acquired bronchiectasis remains controversial. The principal theory is that mechanical dilatation of the bronchi is followed by weakening of the bronchial walls and failure of adequate drainage with resultant infection of the bronchi. Pathologic changes in the bronchial tree are thus brought about by retention of the exudate with further obstruction and infection. Bronchial dilatation, therefore, is not the sole cause of bronchiectasis. It is only when such dilatation is accompanied by inadequate drainage facilities and formation of a plug of normal secretions and exudates that bronchial infection and its symptoms are manifested. The initial cause of the disease may be the presence of foreign bodies, broncholiths, bronchopleural fistulas, pneumoconiosis, enlarged lymphnodes and tuberculous fibrosis. Although broncho-pneumonia is considered a precursor of bronchiectasis, virus pneumonia is not believed to be an etiologic agent, although cases of pseudo-bronchiectasis, temporary bronchial dilatation, have been described in virus pneumonia. Infectious diseases such as measles or whooping cough may cause a bronchiectasis. Thus any bronchial infection of infancy or childhood may be followed by atelectasis, pneumonitis, bronchitis and finally, bronchiectasis.

Sinusitis may precede, accompany or follow bronchiectasis but few believe that bronchiectasis is secondary to paranasal sinus infection.

Bronchiectasis secondary to tuberculosis is a relatively frequent pathologic finding and is often unrecognized. It results from a combination of bronchial and pulmonary factors. Tuberculous lesions of the bronchi with associated peribronchial obstruction produce interference with pulmonary ventilation and drainage with resultant retention and stagnation of secretions. Chronic pulmonary fibrosis produces loss of elastic tissue and reduction of lung volume. Another factor often unappreciated is the effect of tuberculous caseous pneumonia or bronchopneumonia which by decreasing aerated parenchyma and distensibility lowers intrathoracic pressure and exerts traction on the bronchial wall, producing ectasia.

*Pathology.*—The essential process in bronchiectasis has been described as an ulcerative lesion in the bronchi with destruction of the epithelium, muscle and elastic fibers of the bronchi and frequent extension of the destructive process into the surrounding tissues of the lung. This process is furthered by stenosis of the bronchus, a stenosis causing retention of infective secretions and weakening of the elastic tissues, resulting in dilatation of the bronchial walls. Two main types

of bronchiectasis are recognized the saccular and the cylindrical

Bronchiectasis may be unilateral or bilateral and may involve segments of one or more lobes It occurs most frequently in the lower lobes particularly in the left lung Bronchiectasis in the lingula of the left upper lobe often occurs simultaneously with bronchiectasis *in the left lower lobe It occurs* less frequently in the right bronchus since the latter is a more direct continuation of the trachea and drainage is more efficient whereas the left bronchus is not only constricted by the left pulmonary artery but is narrower and comes off the trachea at a more acute angle than does the right lower lobe bronchus

*Incidence* —The incidence of bronchiectasis is difficult to determine Most cases develop in childhood or early adult life

*Clinical Manifestations* —The first symptom is usually a persistent cough Sputum sometimes fetid or foul may be expectorated in amounts varying from a few ounces to 1000 cc daily The sputum is more copious in the morning, owing to retention of secretions during the night The patient may be free from expectoration for the remainder of the day At times the sputum is streaked with blood and at irregular intervals, there may be a severe hemoptysis amounting sometimes to a pint of blood This may cause a suspicion of the presence of tuberculosis or a lung abscess The hemoptysis is rarely followed by any significant aftereffects except that of alarm on the part of the patient or his family It is seldom fatal When the sputum is foul it gives rise to a persistent offensive breath Slight fever may accompany the cough and hemoptysis Clubbing of the fingers often to slight degree *with incurvation of the nails has been ob*served in long standing cases

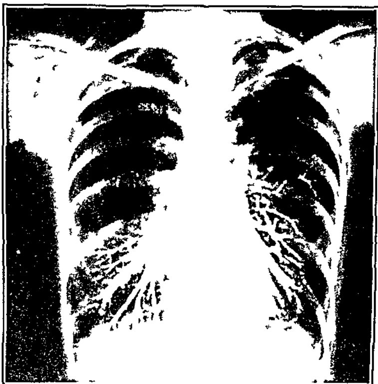

Fig 148 —Bilateral cylindrical bronchiectasis in lower lobes

Except for recurrent attacks of bronchitis and bronchopneumonia which occur mostly in the winter months the patient may have the appearance of general good health for long periods of time after onset of the disease without evident change in respiratory rate significant rise in temperature, or

tachycardia Chest pain is uncommon The disease may be present for years without causing physical deterioration The physical signs are not pathognomonic and are usually those of chronic pneumonitis or fibrosis or those of the associated or complicating disease (bronchopneumonia empyema or lung abscess) Palpation reveals tactile fremitus increased in cases of extensive pulmonary fibrosis or decreased when the pleura is markedly thickened Resonance is the rule on percussion except in the presence of peribronchial infiltration where dullness is noted Hyperresonant to tympanitic notes are elicited if the dilated bronchi are near the surface but dullness is found when the cavities are filled with pus Many types of rales may be heard particularly in advanced cases but not consistently

Examination of the sputum reveals such organisms as are found in bronchitis Those most characteristic are fusiform bacilli spirilla and anaerobic bacilli streptococcus hemolyticus and nonhemolyticus streptococcus viridans staphylococcus albus and aureus pneumococcus and hemophilus influenzae

*Diagnosis* —Diagnostic measures include a careful study of the history of susceptibility to colds pneumonitis or tuberculosis and the possibility of the presence of a foreign body supplemented by a physical examination and laboratory bronchoscopic and *x* ray studies

Routine roentgenologic examination gives little information In severe cases it may show a depressed diaphragm peribronchial fibrosis and irregular fibrotic mottling Cyst like shadows in the apical area of the upper lobe may represent emphysematous blebs while some may indicate bronchiectatic dilatations often resulting from tuberculous processes The appearance of large multiple cysts are suggestive of congenital bronchiectasis It must be remembered that a normal roentgenogram does not indicate the absence of bronchiectasis

Bronchography affords the only sure evidence of bronchiectasis and consists of instillation of iodized oil into the bronchial tree after thorough postural drainage By outlining in turn the bronchioles of each lobe the type and extent of the disease can be determined Involved segments reveal bronchiolar dilatation of a cylindrical (tubular) or saccular (grape like cluster) type the extent of involvement being a guiding factor in the selection of cases for surgery

Bronchoscopic inspection may reveal the presence of foreign bodies or other obstruction It is valuable in investigating ectasia produced by bronchial lesions in revealing the character of the exudate and in detecting bronchial orifices from which the exudate originates

*Prophylaxis* —It is now possible in large measure to prevent bronchiectasis Early diagnosis and proper care of measles whooping cough and bronchopneumonia will prevent many cases of the disease Control of sinus infection prompt removal of foreign bodies endothoracic new growths and bronchial strictures (where possible) will do much to prevent interference with bronchial drainage and dilatation of the bronchi

*Medical Treatment* —Treatment of bronchiectasis is both medical and surgical Since the anatomical changes produced by bronchiectasis are irreversible the medical therapy must be chiefly symptomatic Medical measures must be directed not only toward relief of symptoms but toward removal of etiologic factors

Symptoms in some instances can be relieved by proper medication and postural drainage Postural drainage is widely advocated since this procedure produces a maximal evacuation of secretion Patients are advised to lean over the edge of the bed to allow the exudate to accumulate in the bronchi and gravitate to the trachea from which is is easily expectorated This should be done three times daily Adequate postural drainage in some cases brings such dramatic relief that patients are able to continue their activities for years without great discomfort Hanging from the hips over the side of the bed with the head almost touching the floor or bending over a stool in a like manner for fifteen minutes will usually loosen the secretions so that they can be expectorated on assuming a sitting position Postural drainage is most helpful when performed just before retiring and again on rising in the morning Expectorants help to decrease the viscosity of the secretions

of bronchiectasis are recognized the saccular and the cylindrical

Bronchiectasis may be unilateral or bilateral and may involve segments of one or more lobes It occurs most frequently in the lower lobes particularly in the left lung Bronchiectasis in the lingula of the left upper lobe often occurs simultaneously with bronchiectasis in the left lower lobe It occurs less frequently in the right bronchus since the latter is a more direct continuation of the trachea and drainage is more efficient whereas the left bronchus is not only constricted by the left pulmonary artery but is narrower and comes off the trachea at a more acute angle than does the right lower lobe bronchus

*Incidence* —The incidence of bronchiectasis is difficult to determine Most cases develop in childhood or early adult life

*Clinical Manifestations* —The first symptom is usually a persistent cough Sputum sometimes fetid or foul may be expectorated in amounts varying from a few ounces to 1000 cc daily The sputum is more copious in the morning, owing to retention of secretions during the night The patient may be free from expectoration for the remainder of the day At times the sputum is streaked with blood and at irregular intervals there may be a severe hemoptysis, amounting sometimes to a pint of blood This may cause a suspicion of the presence of tuberculosis or a lung abscess The hemoptysis is rarely followed by any significant aftereffects except that of alarm on the part of the patient or his family It is seldom fatal When the sputum is foul it gives rise to a persistent offensive breath Slight fever may accompany the cough and hemoptysis Clubbing of the fingers often to slight degree with incurvation of the nails has been observed in long standing cases

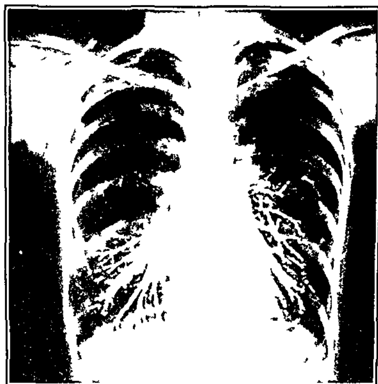

FIG 148 —Bilateral cylindrical bronchiectasis in lower lobes

Except for recurrent attacks of bronchitis and bronchopneumonia which occur mostly in the winter months the patient may have the appearance of general good health for long periods of time after onset of the disease without evident change in respiratory rate significant rise in temperature or

The course of bronchiectasis without surgical therapy is steadily downward with possible development of such complications as heart failure, brain and lung abscesses, empyema, amyloidosis, pneumonitis, pneumothorax and pulmonary fibrosis with emphysema.

If bronchiectasis is initiated in early adulthood and is not treated surgically, life expectancy beyond middle age can hardly be hoped for.

After surgical intervention, the mortality rate is low and prognosis for complete recovery is good. This is particularly true now that the use of the antibiotics has become common both before and after operation.

## Bronchial Stenosis and Obstruction

*Definition.*—Bronchial obstruction is mechanical interference with normal ventilation and drainage of the lung. Bronchial stenosis is narrowing of the lumen of the bronchi.

*Pathologic Physiology.*—The intrathoracic pressure during quiet breathing in the healthy individual is sub-atmospheric during both phases of the respiratory cycle except during coughing or straining. However, in the presence of obstruction to the free flow of air into and out of the lungs, strong inspiratory and forced expiratory efforts, or coughing and muscular straining, the intrathoracic and intrapulmonary pressure may be increased ten times. Normally the lumen of the bronchus widens during inspiration and narrows during expiration. When the air intake is increased by respiratory demands and expiration is interfered with, as in cases of stenosis, an increasing amount of air is trapped in the lung. Respiratory balance is restored only if the intrapulmonary air behind the occlusion overcomes the resistance to expiration. Normal bronchi are directly related to ventilation and drainage of the lung, to intrapulmonary pressure and to circulatory balance.

Cough, the function of which is removal of secretions and obstructions, produces maximum reduction of the bronchial diameter and so prevents air from escaping. This reduction of the bronchial diameter during cough is irregular, the walls of the bronchi not remaining parallel, so that stenosis may progress to complete obstruction. Complete stenosis usually results in atelectasis.

*Etiology.*—Bronchial stenosis may be congenital or acquired. When *congenital*, pressure on the bronchi during fetal development may have brought about a deformity of the whole lung and of the larger bronchi and their alveoli, so that the lung becomes a vast unilocular or multilocular cyst. An anomaly developed later in fetal life may affect only a few smaller bronchi and cause only small intrapulmonary cysts. Such cysts may lie against the wall of a large bronchus and compress its lumen. But this is rare.

*Acquired bronchial stenosis* may be *extrabronchial* (as a result of pressure on or invasion of the lumen by a pathologic process in adjoining areas) or *endobronchial* (as a result of intrinsic disease of the air passages) or *intrabronchial* (as a result of occlusion by foreign bodies). The stenosis is brought about by swelling of the mucosa, by obstructive exudates which accumulate when cough is ineffective, or by outward or inward increase in pressure so that partial or complete obstruction ensues.

*Intrabronchial* stenosis may be caused by foreign bodies, plugs of adhesive exudates, inflammatory lesions or tumors.

Bronchial stenosis frequently develops after severe or chronic infections of the tracheobronchial tree, such as measles, whooping cough, pneumonia, influenza, scarlet fever and asthmatic bronchitis.

Tumors usually occur in only one lobe. Tuberculous granulations and non-tuberculous inflammatory constrictures usually develop in only one of the large bronchi.

Stenosis of the middle bronchi is generally caused by the presence of small foreign bodies or by diffuse sclerosing processes such as pneumoconiosis and tuberculosis. Blockage of these smaller bronchi causes the alveoli to be blown out into emphysematous blebs. On the other hand, constriction of the bronchioles and obstruction of their lumen by swelling of the mucosa may follow bronchitis and influenzal infections or inhalation of fumes, smoke or gases.

*Symptoms and Signs.*—Symptoms in the early stages of bronchial stenosis may be lacking except for slight discomfort on exer-

while postural drainage is being carried out This procedure is the best method of treatment when the sputum is foul and annoying to the patient

Repeated bronchoscopic aspirations of sticky secretions are sometimes found valuable in advanced cases in which postural drainage has proved inadequate Such aspiration may bring relief for weeks if followed by postural drainage

Bed rest is advisable in the presence of fever and distressing cough The diet should be adequate and have a high protein a high caloric and a high *vitamin content*

Antimicrobial drugs although of no permanent effect on bronchiectasis are of great value in treating acute episodes of respiratory-tract infections and in improving the general condition of the debilitated bronchiectatic patient Cough and the amount of retained exudates are reduced the temperature is lowered and given postoperatively, the antibiotics may prevent such complications as emphysema atelectatic pneumonia, *and hematogenous dissemination of the in*fection

*Surgical Therapy* —Only resection of the affected pulmonary tissues can bring certain and permanent cure Internist and surgeon should work together, for physicians who routinely advise against surgical interference in bronchiectatic patients are assuming a great responsibility Since bronchiectasis is an irreversible process it must always be borne in mind that medical measures such *as postural drainage* and use of the antimicrobial drugs are primarily palliative only Except in patients with minimal disease only complete removal of the involved area is permanently effective Unfortunately many patients are seen when the bronchiectasis has become so extensive that neither lobectomy nor pneumonectomy will be effective

The age of the patient and particularly the extent of the disease determine whether the operation should be *performed* Pulmonary resection is highly successful in children, who have a more rapid and more nearly complete recovery than older patients Postoperative morbidity and mortality increase with the age of the patient

Patients in poor general health must first be brought into good condition and concurrent diseases must be brought *under control* before operation is attempted Aerosol therapy is advocated for one week before the operation or until the sputum is reduced to minimum and for an indefinite period after the operation Bronchoscopic aspiration immediately preceding operation is recommended

Bilateral bronchiectasis is often a contraindication for operation but a number of patients have had bilateral operations that *have proved successful In bilateral bron*chiectasis, only one lobe is removed in the first stage later when compensatory adjustments have been made the lobe on the other side may be removed The operation, being elective is preferably performed after the winter and early spring months, during which respiratory infections are most common

Lobectomy is the method of choice in treatment of most types of bronchiectasis *Lobectomy and partial or total pneumonec*tomy now have a death rate of only about 3 per cent

Bilateral lobectomy has a high mortality rate since the patient is subjected to two operations and while convalescing from the first operation is liable to secondary infection from the remaining bronchiectatic infection Souders noted that when about 70 per cent of the disease is in one lung removal of the diseased portion of that lung *may result in such improvement that* resection of the remaining diseased areas may not be necessary If found necessary the second operation can be performed later Usually bilateral surgery is performed in two stages six months to one year elapsing between operations

*Prognosis* —The prognosis is poor in non treated or unsuccessfully treated cases of bronchiectasis The patient may contract the disease early in life yet live to old age but in all the years between he may be extremely uncomfortable and unhappy perhaps totally disabled Protracted invalidism economic insecurity and a lonely hopeless life may lead to a psychopathic personality and prove a greater problem to the physician than the disease itself

*Pathologic Physiology.*—When a non-opaque body lodges in the bronchus severe edema of the bronchial mucosa follows increasing the bronchial obstruction. Since the bronchi widen on inspiration only partial obstruction may be caused by the foreign body and sufficient space remains between it and the bronchial wall to allow entrance of air (ball valve mechanism) but on expiration with narrowing of the bronchus the edema more or less prevents escape of the air from the lung. This in turn leads to retention of excess air in the segment immediately distal to the bronchus a condition eventually leading to emphysema. This is called the expiratory check valve mechanism which becomes complete as irritation leads to plugging of the bronchus (stop-valve mechanism). When the foreign body has thus finally completely blocked the bronchus the air below the foreign body is slowly absorbed atelectasis follows. The stop-valve mechanism may develop rapidly within a few hours especially when the foreign body is vegetable matter (like a bean) and swells rapidly. Occasionally the foreign body causes a chemical action as well producing further irritation of the tissues sometimes the action is biochemical or allergic.

*Signs and Symptoms.*—With distension of the lung the percussion note becomes hyperresonant or tympanitic voice sounds are absent and breath sounds are heard only when some inspired air has penetrated the blocked-off segment of the lung before distention is complete. Pneumothorax may be suspected. Seldom however does the contained air burst through a weakened portion of the lung surface to create a pneumothorax. Roentgen examination reveals transparency of the affected side because of its excess air content. The heart and mediastinum are displaced toward the normal side by the distended lung this depresses the diaphragm on the affected side and restricts its movements. Movement on the sound side is therefore increased and at the end of expiration this contrast in the transparency of the two lungs is quite evident. This is not noted during inspiration.

The symptoms depend on the size and nature of the foreign body. The bronchial lumen because of irritation and inflammation of the mucous membrane may be obstructed and in turn cause an intense inflammatory reaction. The position of the foreign body and the retained exudate together with emphysema and atelectasis and the occasional shifting of the object all tend to influence the general clinical picture. The lower down the foreign body goes in the respiratory tract the less the irritation and discomfort. If it is in the larger bronchi and moving up and down with respiration irritation of the mucous membrane of the trachea will produce a cough. Yet as the object comes to rest the patient may be unaware of its continued presence for an extended period or until secondary symptoms arise. It may be weeks or months before complete blockage takes place.

In addition to cough there may be dyspnea and pain. Fever usually develops later. Wheezing is heard in most cases. A symptomless period may be followed by severe cough blood streaked sputum a metallic taste and a specific odor depending on the nature of the foreign body. Vegetable matter may cause laryngotracheal bronchitis attended by irregular fever. When symptoms develop the roentgenogram may suggest the presence of an unresolved pneumonia an obvious atelectasis bronchiectasis abscess or empyema may be diagnosed but the true cause is often unsuspected.

Prognosis is good if spontaneous expulsion of the foreign body occurs but this is rare. Recovery is generally assured if removal of the foreign body is prompt. The younger the patient the more dangerous is the condition particularly if the object is of vegetable matter since such material may cause suppuration.

*Treatment.*—The only cure possible is removal of the foreign body by means of bronchoscope. This requires skilled operators. Inverting the patient and shaking him an old family remedy is dangerous since the object may lodge in the glottis and cause suffocation.

ADAMS R and FICARRO B J Appraisal of Surgery in Treatment of Bronchiectasis J A M A 1947 *134* 240

tion Wheeze, dyspnea, and cough are the most common symptoms Wheeze is noted invariably in progressive bronchial obstruction Jackson observes that the patient with one lung entirely atelectic may be short of breath only on exertion if the other lung is correctly functioning Obstructive emphysema causes dyspnea only when both lungs are affected When only one major bronchus is involved the dyspnea is not severe and the patient is uncomfortable only on exertion Breathlessness is very apparent on exertion in high stenosis of the trachea or both bronchi at the bifurcation but disappears when the patient is lying down

Stridor, which is loud in stenosis of the trachea and sometimes in stenosis at the bifurcation is absent in diffuse stenosis of the small bronchi a point of differentiation according to Floesser

Stenosis of the larger bronchi is characterized by a loud brassy nonproductive cough of mediastinal or tracheal irritation When cough is productive the sputum is copious watery and frothy, if the obstruction is sufficiently severe to cause distal atelectasis If the sputum is blood streaked the phenomenon is due to the underlying process Abundant thin purulent sputum may alternate with a dry unproductive cough and indicate an intermittent stenosis Foul and purulent sputum is indicative of an infective process

*The clinical finding of a localized wheeze is* suggestive of bronchial stenosis especially when heard at the end of a forced expiration

The degree of resonance and dullness vary with the extent of complicating obstructive emphysema and atelectasis Atelectasis should be suspected when findings indicate displacement of the trachea heart mediastinum and chest wall

*Diagnosis* —The diagnosis of bronchial obstruction should be suggested when the characteristic signs and symptoms are observed and confirmed by fluoroscopic radiographic and bronchoscopic examinations Roentgenograms may demonstrate the presence and site of the obstruction and indicate the condition of the adjacent pulmonary tissues but they cannot show the cause of the stenosis Bronchoscopy is necessary in every suspected case of broncho stenosis It frequently reveals the site, degree, and extent of the obstruction and often demonstrates extrabronchial pressure and the presence of intrabronchial tumors ulceration, and scars

Bronchography is not advisable where possible aggravation of the occlusion might result Laminagrams are valuable in demonstrating narrowing of a bronchus

*Treatment* —Definitive treatment depends on the cause of the obstruction Peroral aspiration of the tracheobronchial tree with restoration of normal drainage by ciliary motion tussive squeeze, and bechic blast—this is the only method of obtaining relief of bronchial obstruction and, for this, bronchoscopic aspiration is necessary The bronchoscope is also used to study the bronchial conditions following aspiration of accumulations Jackson finds that direct laryngoscopic and bronchoscopic aspiration will, with ample power supplied by the negative pressure pump remove even semisolid exudates

Medical care is essential in most cases to restore normal drainage Usually patients are so relieved after bronchoscopic aspiration that they immediately enjoy normal activities Such patients however require a strictly enforced regime of medical care and management, with rest in bed for from 12 to 18 hours daily a well balanced diet taken in three meals a day vitamin therapy, *and in allergic patients desensitization* Autogenous vaccines and antibiotics may be helpful Opiates sedatives and expectorants should be avoided

## Foreign Bodies in the Bronchi

The lodging of foreign bodies in the air and food passages is very common Ninety per cent of the cases of foreign bodies lodged in the bronchi are said to occur in children under two years of age One of the principal reasons for this is children s carelessness in putting objects in the mouth haste in eating and swallowing and playing while eating and drinking The symptoms may be long delayed or may be only slightly annoying for many years Metal objects are often tolerated without symptoms for they usually become covered with a calcareous concretion

### Ventilation and Ventilatory Insufficiency

Ventilation can be considered a mechanical phenomenon because air flow in the lungs is the result of variations in pressure in the alveoli and tracheobronchial tree induced by periodic movements of an air pump consisting of the chest wall diaphragm and other muscular structures The range of variation of alveolar pressure during the respiratory cycle is quite small normally from a few mm Hg below to a few mm Hg above atmospheric pressure It is commonly accepted that stresses exerted by this air pump produce variations in intrapleural pressure also which are of greater amplitude than those occurring in the alveoli One must emphasize however, that the microscopic film of fluid present in the pleural space creates cohesive forces between the two sheets of pleura which prevent their separation and that under normal conditions no intrapleural pressure can be measured during the respiratory cycle Pleural pressure variations can be measured only after introduction of air and creation of an intrapleural space Under these conditions the pleural pressure is a reflection of the balance of opposing forces created by (*a*) the moving chest bellows and (*b*) the elastic lung

During inspiration the lungs enlarge as shown by Keith according to a definite pattern which is determined by the actual structure of the lungs on the one hand and the movements of the chest bellows on the other The great fissure is of functional significance in this regard The two upper lobes together with the middle lobe on the right are expanded by the action of the muscular and bony structures of the neck and shoulder girdle the first five ribs and the upper two-thirds of the sternum This section of the chest moves upward and forward on inspiration expanding the underlying lung in exactly the same manner Expansion of the two lower lobes is quite different being dependent upon the action of the diaphragm and of the lower ribs excepting the 11th and 12th which are a part of the abdominal wall When the intercostal muscles attached to these ribs contract on inspiration there occurs in addition to a forward movement of the lower sternum considerable lateral displacement of the lower chest The diaphragm acts much like a piston moving downward and forward on contraction displacing the abdominal contents before it As a result of these motions the lower lobes are expanded laterally forward and downward Their apical regions being relatively fixed this expansion is accomplished with considerable sliding of the visceral over the parietal pleura The musculature of the abdominal wall itself also plays an active although not always obvious part in respiration by relaxing during inspiration and contracting during expiration and thus must be considered a part of the chest bellows This is most apparent during forced expiration when strong contraction of the abdominal musculature occurs

Normal ventilation necessitates expenditure of energy on the part of these various muscles of respiration in order that certain resistive forces be overcome These forces include the elasticity of the lungs and chest wall the viscous and turbulent resistance of air movement in the respiratory passages and the resistance to deformation always present in living tissue a property that must be differentiated from elasticity Kinetic energy imparted to the air is probably of negligible importance as is the energy involved in acceleration and deceleration of the entire system even though during maximum breathing efforts peak rates of air flow have been shown to reach as much as 400 liters per minute The resistive forces are normally quite small in comparison to the motive powers of the muscles of respiration In terms of air flow this is manifest in the fact that the chest bellows is ordinarily capable of providing an amount of ventilation far greater than anything required by bodily activity This means that under normal conditions there is always an excess of ventilatory capacity over the ventilation required The excess ventilatory capacity when expressed as the difference between observed ventilation and the measured maximum voluntary or reflex breathing capacity is known as the *breathing reserve* This is of considerable importance in any consideration of pulmonary function because in nor-

# PULMONARY FUNCTION IN SUB-ACUTE AND CHRONIC DISEASES OF THE LUNGS

BY ANDRE COURNAND M D AND JOHN R WEST M D

## PRIMARY FUNCTION OF THE LUNGS

An appreciation of the clinical manifestations of subacute and chronic diseases of the lungs necessitates first an understanding of the various factors involved in pulmonary function and second an awareness of the means by which these factors may be altered by disease

Aeration of the blood the primary function of the lungs is a complicated process having three major components These are (1) pulmonary ventilation or the mass movement of air into and out of the lungs (2) the exchange of oxygen and carbon dioxide between this air and the blood and (3) the mechanisms by which ventilation is regulated so as to provide the amount of respiratory gas exchange demanded by the metabolic needs of the body That these components are closely interrelated is apparent Nevertheless this division is a useful one for purposes of discussion and will be adhered to in the following brief outline of pulmonary function and dysfunction

this, regional blood flow in the lungs is readily influenced by local mechanical factors. Consequently narrowing or obliteration of smaller vascular channels as well as local variations in pulmonary elasticity induced by pathologic change may greatly alter the distribution of capillary blood to the alveoli. Furthermore in pulmonary disease in which large and small air ways are variably obstructed uneven distribution of inhaled air may become marked and may lead to hypoventilation of certain areas with considerable reduction in oxygen tension and elevation of carbon dioxide tension in the alveoli concerned. When these disturbances in the distribution of air and blood in the lungs affect significant numbers of alveoli defective gas exchange results.

Whenever ventilation is maintained but perfusion of alveoli is reduced or obliterated gas exchange across the membrane is reduced or eliminated. Physiologically, ventilation of such alveoli is indistinguishable from ventilation of the tracheobronchial tree (the anatomic dead space) hence the presence of large numbers of these alveoli results in increased *dead space like ventilation*. Excessive dead space ventilation throws a greater than normal burden in respect to gas exchange upon remaining normal alveoli and adequate carbon dioxide elimination can take place only when the normally perfused alveoli are hyperventilated (Fig 149). An adequate oxygen intake however with only slight reduction in arterial oxygen saturation can occur *without* hyperventilation in most instances of excessive dead space ventilation because of the special affinity of blood for oxygen in the range of alveolar oxygen partial pressures which would be found.

Conversely whenever alveolar ventilation is reduced while perfusion is maintained at a normal level the blood does not become fully arterialized in the capillaries. The effect upon arterial blood of mixing this fraction of capillary blood (partially oxygenated) with the remainder (fully oxygenated) is similar to that of a true veno arterial shunt the magnitude of which may be estimated. This virtual shunt together with actual right to left shunts passing through bronchial and thebesian veins has been termed *venous admixture*. Venous admixture results in arterial anoxia as well as a *tendency* towards carbon dioxide retention. The latter may not be realized if sufficient hyperventilation of remaining well ventilated, perfused alveoli occurs. Arterial anoxia due to venous admixture cannot however be corrected to any significant degree by hyperventilation of normal alveoli (Fig 149).

The physical properties of the alveolo capillary membrane its total area in the lungs and the partial pressure differences on either side of the membrane determine the rates at which respiratory gases diffuse between alveolar air and blood. The membrane is vastly more permeable with respect to carbon dioxide than it is with respect to oxygen a reflection of the difference in solubility of the two gases in watery solutions but even so the normal membrane never offers a significant barrier to oxygen transfer. If the membrane is altered by disease however it may inhibit the diffusion of oxygen to a variable extent. Even in the presence of considerable disease this impairment will result in significant arterial anoxia only under conditions in which there is a large amount of oxygen to be transferred per unit time as for example during physical exercise or under conditions wherein the inspired air has a low oxygen concentration as in residence at high altitudes. In some rare instances of severe non homogeneous alterations of the alveolo-capillary membrane throughout the lung oxygen diffusion may become so impaired in some areas that transport of this gas ceases entirely under physiologic conditions and transport of carbon dioxide becomes impeded. Ventilation of alveoli involved in such a process contributes to dead space ventilation and perfusion to venous admixture. Consequently in these instances arterial anoxia may be present at rest and carbon dioxide retention may occur.

From these considerations it is apparent that impaired gas exchange in pulmonary disease can be attributed to one or more mechanisms (1) ventilation of poorly perfused areas—dead space like ventilation (2) perfusion of poorly ventilated areas—venous admixture and (3) impaired diffusion of oxygen across the alveolar capillary membrane—reduction in oxygen diffusing capac-

mal individuals and in most patients with pulmonary disease there appears to be a definite correlation between the size of the breathing reserve and the consciousness of difficult breathing *i e* dyspnea Obviously, the breathing reserve can be reduced in either of two ways *i e* increasing the breathing requirement or decreasing the breathing capacity or by both No matter what the cause or what the mechanism whenever breathing reserve is reduced to such an extent that dyspnea ensues *ventilatory insufficiency* can be said to be present For example bronchospasm and bronchiolar obstruction found in asthma and pulmonary emphysema increase the viscous and turbulent resistance to air movement in the smaller respiratory passages and, therefore lead to great reduction in ventilatory capacity In consequence breathing reserve may by slight exercise be reduced below the level at which dyspnea appears In some of these patients ventilatory capacity may become so impaired that dyspnea is present at rest Conversely other pulmonary diseases to be discussed in more detail later are characterized by reduction in breathing reserve as a result of the increase in ventilatory requirement they engender Although the mechanism is distinctly different the result is the same *viz* a decrease in the breathing reserve and production of dyspnea

It must be mentioned that the rhythmic action of the chest bellows affects pulmonary blood flow (and therefore cardiac output) as well as air flow During inspiration the amount of blood flowing into the lungs increases, while the outflow diminishes In expiration the reverse process occurs *i e* inflow decreases while left heart output is augmented

## Gas Exchange and Alveolar Respiratory Insufficiency

Respiratory gas exchange is a physicochemical process which depends upon differences in partial pressure of oxygen and carbon dioxide on either side of the structures separating air and blood in the lung *i e*, the alveolo-capillary membrane as well as the physical properties and the area of this membrane

Because the amount of air taken into the lungs in a single breath during quiet breathing (resting tidal volume) is quite small in relation to the amount of air remaining in the lungs at the end of a quiet expiration the composition of alveolar air remains fairly constant throughout the respiratory cycle At sea level the normal values approximately, for the partial pressure of the respective gases present are carbon dioxide 39 mm Hg, oxygen 103 mm Hg, water vapor 47 mm Hg nitrogen and other inert gases 571 mm Hg In mixed venous blood entering the pulmonary capillary the partial pressure of oxygen is considerably lower and that of carbon dioxide slightly higher than these values, being approximately 35 and 45 mm Hg respectively These pressure differences bring about gas exchange *i e*, diffusion of carbon dioxide from blood into alveolar air and diffusion of oxygen from alveolar air into blood Capillary blood leaving the alveoli is as a result of this exchange in nearly perfect gaseous equilibrium with alveolar air in respect to carbon dioxide oxygen, and nitrogen under normal circumstances Inasmuch as the partial pressure of nitrogen in the blood is not affected by gas exchange it is apparent that the total gas pressure in the venous blood is considerably less than atmospheric pressure

The concentrations of the respiratory gases in alveolar air and capillary blood are dependent in large part upon the efficiency of alveolar ventilation on the one hand and the adequacy of alveolar perfusion with blood on the other In the normal lung neither inhaled air or mixed venous blood is *uniformly* distributed to all functioning alveoli but the degree to which distribution is impaired is slight and therefore relatively few alveoli are well perfused but poorly ventilated or poorly perfused but well ventilated This normal relationship between alveolar ventilation and perfusion is however subject to considerable alteration by disease In this respect emphasis must be placed upon the most distinctive characteristic of the pulmonary circulation namely that it is a low pressure system Because of

this, regional blood flow in the lungs is readily influenced by local mechanical factors. Consequently, narrowing or obliteration of smaller vascular channels as well as local variations in pulmonary elasticity induced by pathologic change may greatly alter the distribution of capillary blood to the alveoli. Furthermore, in pulmonary disease in which large and small air ways are variably obstructed, uneven distribution of inhaled air may become marked and may lead to hypoventilation of certain areas with considerable reduction in oxygen tension and elevation of carbon dioxide tension in the alveoli concerned. When these disturbances in the distribution of air and blood in the lungs affect significant numbers of alveoli, defective gas exchange results.

Whenever ventilation is maintained but perfusion of alveoli is reduced or obliterated, gas exchange across the membrane is reduced or eliminated. Physiologically, ventilation of such alveoli is indistinguishable from ventilation of the tracheobronchial tree (the anatomic dead space); hence the presence of large numbers of these alveoli results in increased *dead space like ventilation*. Excessive dead space ventilation throws a greater than normal burden in respect to gas exchange upon remaining normal alveoli, and adequate carbon dioxide elimination can take place only when the normally perfused alveoli are hyperventilated (Fig. 149). An adequate oxygen intake, however, with only slight reduction in arterial oxygen saturation can occur *without* hyperventilation in most instances of excessive dead space ventilation because of the special affinity of blood for oxygen in the range of alveolar oxygen partial pressures which would be found.

Conversely, whenever alveolar ventilation is reduced while perfusion is maintained at a normal level, the blood does not become fully arterialized in the capillaries. The effect upon arterial blood of mixing this fraction of capillary blood (partially oxygenated) with the remainder (fully oxygenated) is similar to that of a true veno-arterial shunt, the magnitude of which may be estimated. This virtual shunt together with actual right to left shunts passing through bronchial and thebesian veins has been termed *venous admixture*. Venous admixture results in arterial anoxia as well as a *tendency* towards carbon dioxide retention. The latter may not be realized if sufficient hyperventilation of remaining well ventilated perfused alveoli occurs. Arterial anoxia due to venous admixture cannot, however, be corrected to any significant degree by hyperventilation of normal alveoli (Fig. 149).

The physical properties of the alveolo-capillary membrane, its total area in the lungs and the partial pressure differences on either side of the membrane determine the rates at which respiratory gases diffuse between alveolar air and blood. The membrane is vastly more permeable with respect to carbon dioxide than it is with respect to oxygen, a reflection of the difference in solubility of the two gases in watery solutions, but even so the normal membrane never offers a significant barrier to oxygen transfer. If the membrane is altered by disease, however, it may inhibit the diffusion of oxygen to a variable extent. Even in the presence of considerable disease this impairment will result in significant arterial anoxia only under conditions in which there is a large amount of oxygen to be transferred per unit time, as for example during physical exercise or under conditions wherein the inspired air has a low oxygen concentration, as in residence at high altitudes. In some rare instances of severe non homogeneous alterations of the alveolo-capillary membrane throughout the lung, oxygen diffusion may become so impaired in some areas that transport of this gas ceases entirely under physiologic conditions and transport of carbon dioxide becomes impeded. Ventilation of alveoli involved in such a process contributes to dead space ventilation and perfusion to venous admixture. Consequently, in these instances arterial anoxia may be present at rest and carbon dioxide retention may occur.

From these considerations it is apparent that impaired gas exchange in pulmonary disease can be attributed to one or more mechanisms: (1) ventilation of poorly perfused areas—dead space like ventilation, (2) perfusion of poorly ventilated areas—venous admixture, and (3) impaired diffusion of oxygen across the alveolar capillary membrane—reduction in oxygen diffusing capac

mal individuals and in most patients with pulmonary disease there appears to be a definite correlation between the size of the breathing reserve and the consciousness of difficult breathing, i e dyspnea. Obviously, the breathing reserve can be reduced in either of two ways, i e increasing the breathing requirement or decreasing the breathing capacity or by both. No matter what the cause or what the mechanism, whenever breathing reserve is reduced to such an extent that dyspnea ensues *ventilatory insufficiency* can be said to be present. For example bronchospasm and bronchiolar obstruction found in asthma and pulmonary emphysema increase the viscous and turbulent resistance to air movement in the smaller respiratory passages and therefore, lead to great reduction in ventilatory capacity. In consequence breathing reserve may by slight exercise be reduced below the level at which dyspnea appears. In some of these patients ventilatory capacity may become so impaired that dyspnea is present at rest. Conversely other pulmonary diseases, to be discussed in more detail later, are characterized by reduction in breathing reserve as a result of the increase in ventilatory requirement they engender. Although the mechanism is distinctly different, the result is the same, viz a decrease in the breathing reserve and production of dyspnea.

It must be mentioned that the rhythmic action of the chest bellows affects pulmonary blood flow (and therefore cardiac output) as well as air flow. During inspiration the amount of blood flowing into the lungs increases while the outflow diminishes. In expiration the reverse process occurs, i e inflow decreases while left heart output is augmented.

## Gas Exchange and Alveolar Respiratory Insufficiency

Respiratory gas exchange is a physicochemical process which depends upon differences in partial pressure of oxygen and carbon dioxide on either side of the structures separating air and blood in the lung, i e the alveolo capillary membrane, as well as the physical properties and the area of this membrane.

Because the amount of air taken into the lungs in a single breath during quiet breathing (resting tidal volume) is quite small in relation to the amount of air remaining in the lungs at the end of a quiet expiration the composition of alveolar air remains fairly constant throughout the respiratory cycle. At sea level the normal values, approximately, for the partial pressure of the respective gases present are: carbon dioxide 39 mm Hg, oxygen 103 mm Hg, water vapor 47 mm Hg, nitrogen and other inert gases 571 mm Hg. In mixed venous blood entering the pulmonary capillary the partial pressure of oxygen is considerably lower and that of carbon dioxide slightly higher than these values, being approximately 35 and 45 mm Hg respectively. These pressure differences bring about gas exchange, i e diffusion of carbon dioxide from blood into alveolar air and diffusion of oxygen from alveolar air into blood. Capillary blood leaving the alveoli is, as a result of this exchange, in nearly perfect gaseous equilibrium with alveolar air in respect to carbon dioxide, oxygen and nitrogen under normal circumstances. Inasmuch as the partial pressure of nitrogen in the blood is not affected by gas exchange it is apparent that the total gas pressure in the venous blood is considerably less than atmospheric pressure.

The concentrations of the respiratory gases in alveolar air and capillary blood are dependent in large part upon the efficiency of alveolar ventilation on the one hand and the adequacy of alveolar perfusion with blood on the other. In the normal lung neither inhaled air or mixed venous blood is *uniformly* distributed to all functioning alveoli but the degree to which distribution is impaired is slight and therefore relatively few alveoli are well perfused but poorly ventilated or poorly perfused but well ventilated. This normal relationship between alveolar ventilation and perfusion is however subject to considerable alteration by disease. In this respect emphasis must be placed upon the most distinctive characteristic of the pulmonary circulation, namely that it is a low pressure system. Because of

this regional blood flow in the lungs is readily influenced by local mechanical factors. Consequently narrowing or obliteration of smaller vascular channels as well as local variations in pulmonary elasticity induced by pathologic change may greatly alter the distribution of capillary blood to the alveoli. Furthermore in pulmonary disease in which large and small air ways are variably obstructed uneven distribution of inhaled air may become marked and may lead to hypoventilation of certain areas with considerable reduction in oxygen tension and elevation of carbon dioxide tension in the alveoli concerned. When these disturbances in the distribution of air and blood in the lungs affect significant numbers of alveoli defective gas exchange results.

Whenever ventilation is maintained but perfusion of alveoli is reduced or obliterated gas exchange across the membrane is reduced or eliminated. Physiologically ventilation of such alveoli is indistinguishable from ventilation of the tracheobronchial tree (the anatomic dead space) hence the presence of large numbers of these alveoli results in increased *dead space like ventilation*. Excessive dead space ventilation throws a greater than normal burden in respect to gas exchange upon remaining normal alveoli and adequate carbon dioxide elimination can take place only when the normally perfused alveoli are hyperventilated (Fig 149). An adequate oxygen intake however with only slight reduction in arterial oxygen saturation can occur *without* hyperventilation in most instances of excessive dead space ventilation because of the special affinity of blood for oxygen in the range of alveolar oxygen partial pressures which would be found.

Conversely whenever alveolar ventilation is reduced while perfusion is maintained at a normal level the blood does not become fully arterialized in the capillaries. The effect upon arterial blood of mixing this fraction of capillary blood (partially oxygenated) with the remainder (fully oxygenated) is similar to that of a true veno arterial shunt the magnitude of which may be estimated. This virtual shunt together with actual right to left shunts passing through bronchial and thebesian veins has been termed *venous admixture*. Venous admixture results in arterial anoxia as well as a *tendency* towards carbon dioxide retention. The latter may not be realized if sufficient hyperventilation of remaining well ventilated perfused alveoli occurs. Arterial anoxia due to venous admixture cannot however, be corrected to any significant degree by hyperventilation of normal alveoli (Fig 149).

The physical properties of the alveolocapillary membrane its total area in the lungs and the partial pressure differences on either side of the membrane determine the rates at which respiratory gases diffuse between alveolar air and blood. The membrane is vastly more permeable with respect to carbon dioxide than it is with respect to oxygen a reflection of the difference in solubility of the two gases in watery solutions but even so the normal membrane never offers a significant barrier to oxygen transfer. If the membrane is altered by disease however it may inhibit the diffusion of oxygen to a variable extent. Even in the presence of considerable disease this impairment will result in significant arterial anoxia only under conditions in which there is a large amount of oxygen to be transferred per unit time as for example during physical exercise or under conditions wherein the inspired air has a low oxygen concentration as in residence at high altitudes. In some rare instances of severe non homogeneous alterations of the alveolo-capillary membrane throughout the lung oxygen diffusion may become so impaired in some areas that transport of this gas ceases entirely under physiologic conditions and transport of carbon dioxide becomes impeded. Ventilation of alveoli involved in such a process contributes to dead space ventilation and perfusion to venous admixture. Consequently in these instances arterial anoxia may be present at rest and carbon dioxide retention may occur.

From these considerations it is apparent that impaired gas exchange in pulmonary disease can be attributed to one or more mechanisms (1) ventilation of poorly perfused areas—dead space like ventilation (2) perfusion of poorly ventilated areas—venous admixture and (3) impaired diffusion of oxygen across the alveolar capillary membrane—reduction in oxygen diffusing capac-

mal individuals and in most patients with pulmonary disease there appears to be a definite correlation between the size of the breathing reserve and the consciousness of difficult breathing, *i e* dyspnea. Obviously, the breathing reserve can be reduced in either of two ways, *i e* increasing the breathing requirement or decreasing the breathing capacity, or by both. No matter what the cause or what the mechanism, whenever breathing reserve is reduced to such an extent that dyspnea ensues *ventilatory insufficiency* can be said to be present. For example, bronchospasm and bronchiolar obstruction found in asthma and pulmonary emphysema increase the viscous and turbulent resistance to air movement in the smaller respiratory passages and therefore lead to great reduction in ventilatory capacity. In consequence breathing reserve may by slight exercise be reduced below the level at which dyspnea appears. In some of these patients ventilatory capacity may become so impaired that dyspnea is present at rest. Conversely, other pulmonary diseases, to be discussed in more detail later, are characterized by reduction in breathing reserve as a result of the increase in ventilatory requirement they engender. Although the mechanism is distinctly different, the result is the same, *viz* a decrease in the breathing reserve and production of dyspnea.

It must be mentioned that the rhythmic action of the chest bellows affects pulmonary blood flow (and therefore cardiac output) as well as air flow. During inspiration the amount of blood flowing into the lungs increases, while the outflow diminishes. In expiration the reverse process occurs, *i e* inflow decreases while left heart output is augmented.

### Gas Exchange and Alveolar Respiratory Insufficiency

Respiratory gas exchange is a physicochemical process which depends upon differences in partial pressure of oxygen and carbon dioxide on either side of the structures separating air and blood in the lung, *i e*, the alveolo capillary membrane, as well as the physical properties and the area of this membrane.

Because the amount of air taken into the lungs in a single breath during quiet breathing (resting tidal volume) is quite small in relation to the amount of air remaining in the lungs at the end of a quiet expiration, the composition of alveolar air remains fairly constant throughout the respiratory cycle. At sea level the normal values approximately, for the partial pressure of the respective gases present are: carbon dioxide 39 mm Hg, oxygen 103 mm Hg, water vapor 47 mm Hg, nitrogen and other inert gases 571 mm Hg. In mixed venous blood entering the pulmonary capillary the partial pressure of oxygen is considerably lower and that of carbon dioxide slightly higher than these values, being approximately 35 and 45 mm Hg respectively. These pressure differences bring about gas exchange, *i e* diffusion of carbon dioxide from blood into alveolar air and diffusion of oxygen from alveolar air into blood. Capillary blood leaving the alveoli is, as a result of this exchange, in nearly perfect gaseous equilibrium with alveolar air in respect to carbon dioxide, oxygen and nitrogen under normal circumstances. Inasmuch as the partial pressure of nitrogen in the blood is not affected by gas exchange it is apparent that the total gas pressure in the venous blood is considerably less than atmospheric pressure.

The concentrations of the respiratory gases in alveolar air and capillary blood are dependent in large part upon the efficiency of alveolar ventilation on the one hand and the adequacy of alveolar perfusion with blood on the other. In the normal lung neither inhaled air or mixed venous blood is *uniformly* distributed to all functioning alveoli, but the degree to which distribution is impaired is slight and therefore relatively few alveoli are well perfused but poorly ventilated or poorly perfused but well ventilated. This normal relationship between alveolar ventilation and perfusion is, however, subject to considerable alteration by disease. In this respect emphasis must be placed upon the most distinctive characteristic of the pulmonary circulation, namely that it is a low pressure system. Because of

This concept is useful also in interpreting changes in ventilation that have been observed in a variety of pulmonary disorders. For example, in certain diseases characterized by a reduction in the oxygen diffusing capacity of the lungs, acute arterial anoxia occurs on exercise and is associated with hyperventilation which is probably due to increased chemoreflex drive. In many of these patients, however, hyperventilation is observed at rest when no arterial anoxia is present. In the majority of such cases the level of blood bicarbonate is reduced (probably a result of repeated bouts of hyperventilation caused by increased physical activity) and the medullary center can therefore be presumed to be *supranormally* sensitive to the carbon dioxide stimulus. Conversely, in certain cases of pulmonary emphysema with arterial anoxia and chronic carbon dioxide retention, ventilation seems to be chiefly controlled by the chemoreflex drive induced by the anoxia because, as a result of an increased blood bicarbonate level, the medullary center has become *infranormally* sensitive to the carbon dioxide stimulus. The reduction in centrogenic drive is most apparent in these cases when the hypoxic stimulus is removed during oxygen therapy or when carbon dioxide tension is artificially elevated in the inhaled air.

## COMMON PATTERNS OF PULMONARY DYSFUNCTION

### Ventilatory Insufficiency

As stated previously, whenever breathing reserve is reduced to such an extent that excessive dyspnea results from ordinary activity, ventilatory insufficiency is present. This is seen in relatively pure form in several conditions, *e.g.*, (1) mild silicosis not complicated by bronchial obstruction or emphysema, (2) discrete nodular fibrosis of other etiologies, (3) radiation fibrosis, (4) benign forms of pulmonary Boeck's sarcoid and (5) other pleuritic and thoracic processes of varying etiologies. Patients with these disorders complain chiefly of exertional dyspnea which is generally mild to moderate and their only important functional characteristic is an abnormal reduction in breathing reserve during exercise. In some cases this reduction is due to excessive ventilation, in others to reduction in ventilatory capacity, but in the majority to a combination of the two factors. Hyperventilation may be present at rest but this is not marked as a rule. Arterial anoxia is not observed nor is carbon dioxide retention; in fact, it is usual to find a mild compensated respiratory alkalosis. The cause of the resting hyperventilation observed in such cases has been attributed to reflex stimulation arising in the lungs and the osteomuscular frame of the chest induced by the pathologic changes. An additional factor, in all probability, is the effect of the commonly found reduction in blood bicarbonate upon the sensitivity of the medullary center to the carbon dioxide stimulus.

### Alveolo-respiratory Insufficiency

(*a*) *Excessive Dead Space Ventilation.*—In isolated form increased dead space ventilation is observed mostly as a result of large pulmonary air cysts which communicate freely with the tracheobronchial tree. It may follow also repeated embolization of the small pulmonary blood vessels as seen in drug addicts. A similar situation will obtain after accidental ligation of a main branch of the pulmonary artery during surgery. In such an instance ventilation will be maintained with practically no gas exchange occurring in the affected lung.

As has been mentioned previously, a large dead space ventilation necessitates hyperventilation of remaining well perfused alveoli in order to maintain adequate carbon dioxide elimination and normal arterial pCO. The hyperventilation observed in such cases is doubtless due to increased centrogenic drive. Symptomatically, excessive dead space ventilation results in dyspnea and this only if the hyperventilation is extreme because ventilatory capacity remains normal as a rule.

(*b*) *Excessive Venous Admixture.*—This is never observed in pure form as a result of chronic pulmonary disease except in the case of pulmonary arteriovenous fistula. In such cases arterial anoxia, resultant cyanosis and secondary polycythemia may be quite severe. Carbon dioxide retention does not

ity Recently developed techniques have made it possible to quantitate these disturbances as they occur in a variety of pulmonary diseases In so doing the essential physio pathologic disturbances in these disorders have been more closely defined and results of treatment can be assayed

### Regulation of Ventilation

Pulmonary ventilation in the normal individual is under two distinct types of control Pitts has classified these as (1) Chemical—which are concerned with the metabolic and homeostatic demands of the body and (2) Nervous—which are concerned with modification of the basic breathing pattern so as to meet the needs of the moment 'Nervous controls include both cortical and hypothalamic influences as well as certain reflex mechanisms the Hering Breuer reflex pressoreceptor reflexes from the aortic arch and the carotid sinus, various protective reflexes, and reflexes from muscle and joint receptors Persistent hyperventilation in the absence of disordered gas exchange as has been observed in certain types of pulmonary fibrosis has been attributed to alteration in intrapulmonary stretch reflexes of this general type Otherwise these mechanisms are of little clinical importance in pulmonary disease

' Chemical controls are those arising in medullary respiratory center and the peripheral chemoreceptors in the aortic and carotid bodies The medullary center is normally extremely sensitive to changes in arterial $pCO_2$ or arterial pHs responding to very small increments in the former or decreases in the latter with an increase in the respiratory stimulus which has been termed Centrogenic drive The peripheral chemoreceptors in the aortic and carotid glomi are on the other hand chiefly concerned with the hyperventilation which occurs as a result of a decrease in arterial oxygen partial pressure Reduction in arterial oxygen tension is always associated with an increase in electrical activity in the afferent nerves of these bodies, but it is only below a certain critical threshold (arterial $pO_2$ less than 60 to 50 mm Hg ) that the increased stimulus arising in these bodies becomes significant in the regulation of ventilation This stimulus, which is transmitted *through* the medullary center, has been termed 'Chemoreflex drive ' Normal ventilation seems to be the result of centrogenic drive chiefly, the strength of the stimulus depending upon the concentrations of carbon dioxide or hydrogen ions in the respiratory center Whether the actual stimulus is molecular carbon dioxide the hydrogen ion, or both is a matter of some dispute Studies of the respiratory effects of acute anoxia in animals and acute and chronic anoxia in man demonstrating that the sensitivity of the medullary center to the carbon dioxide stimulus varies inversely with the level of blood bicarbonate tend to support the concept that the level of medullary center activity depends upon the pH changes induced within the center by the carbon dioxide produced there metabolically The pH change at the center per unit carbon dioxide produced will depend obviously upon the buffering capacity of the media concerned which is probably related to that of blood plasma The buffering capacity of blood plasma is reflected in the amount of bicarbonate present

Certain well known phenomena of respiration during ascent to an after residence at high altitudes are readily explained according to this view Thus sudden anoxia induced by ascension brings about an increased chemoreflex drive and hyperventilation ensues Hyperventilation causes a reduction in alveolar $pCO_2$ and results in rapid elimination of this gas from the blood A temporary respiratory alkalosis ensues during which medullary center activity is reduced and chemoreflex drive possibly potentiated The alkalosis is gradually corrected by a reduction in the bicarbonate content of the blood As the blood bicarbonate level falls during acclimatization the medullary center becomes increasingly sensitive to carbon dioxide produced *in situ* for reasons stated above and as a result the centrogenic drive increases in strength and finally supersedes the chemoreflex drive If the subject at this stage is relieved of arterial anoxia hyperventilation will continue for some time as a result of the increased centrogenic drive

This concept is useful also in interpreting changes in ventilation that have been observed in a variety of pulmonary disorders. For example, in certain diseases characterized by a reduction in the oxygen diffusing capacity of the lungs, acute arterial anoxia occurs on exercise and is associated with hyperventilation which is probably due to increased chemoreflex drive. In many of these patients, however, hyperventilation is observed at rest when no arterial anoxia is present. In the majority of such cases the level of blood bicarbonate is reduced (probably a result of repeated bouts of hyperventilation caused by increased physical activity) and the medullary center can therefore be presumed to be *supranormally* sensitive to the carbon dioxide stimulus. Conversely, in certain cases of pulmonary emphysema with arterial anoxia and chronic carbon dioxide retention, ventilation seems to be chiefly controlled by the chemoreflex drive induced by the anoxia because, as a result of an increased blood bicarbonate level, the medullary center has become *infranormally* sensitive to the carbon dioxide stimulus. The reduction in centrogenic drive is most apparent in these cases when the hypoxic stimulus is removed during oxygen therapy or when carbon dioxide tension is artificially elevated in the inhaled air.

## COMMON PATTERNS OF PULMONARY DYSFUNCTION

### Ventilatory Insufficiency

As stated previously, whenever breathing reserve is reduced to such an extent that excessive dyspnea results from ordinary activity, ventilatory insufficiency is present. This is seen in relatively pure form in several conditions, e.g., (1) mild silicosis not complicated by bronchial obstruction or emphysema, (2) discrete nodular fibrosis of other etiologies, (3) radiation fibrosis, (4) benign forms of pulmonary Boeck's sarcoid and (5) other pleuritic and thoracic processes of varying etiologies. Patients with these disorders complain chiefly of exertional dyspnea which is generally mild to moderate and their only important functional characteristic is an abnormal reduction in breathing reserve during exercise. In some cases this reduction is due to excessive ventilation, in others to reduction in ventilatory capacity, but in the majority to a combination of the two factors. Hyperventilation may be present at rest, but this is not marked as a rule. Arterial anoxia is not observed nor is carbon dioxide retention; in fact, it is usual to find a mild compensated respiratory alkalosis. The cause of the resting hyperventilation observed in such cases has been attributed to reflex stimulation arising in the lungs and the osteomuscular frame of the chest induced by the pathologic changes. An additional factor in all probability is the effect of the commonly found reduction in blood bicarbonate upon the sensitivity of the medullary center to the carbon dioxide stimulus.

### Alveolo-Respiratory Insufficiency

(*a*) *Excessive Dead Space Ventilation.*—In isolated form increased dead space ventilation is observed mostly as a result of large pulmonary air cysts which communicate freely with the tracheobronchial tree. It may follow also repeated embolization of the small pulmonary blood vessels as seen in drug addicts. A similar situation will obtain after accidental ligation of a main branch of the pulmonary artery during surgery. In such an instance ventilation will be maintained with practically no gas exchange occurring in the affected lung.

As has been mentioned previously, a large dead space ventilation necessitates hyperventilation of remaining well perfused alveoli in order to maintain adequate carbon dioxide elimination and normal arterial $pCO_2$. The hyperventilation observed in such cases is doubtless due to increased centrogenic drive. Symptomatically, excessive dead space ventilation results in dyspnea and this only if the hyperventilation is extreme because ventilatory capacity remains normal as a rule.

(*b*) *Excessive Venous Admixture.*—This is never observed in pure form as a result of chronic pulmonary disease except in the case of pulmonary arteriovenous fistula. In such cases arterial anoxia, resultant cyanosis and secondary polycythemia may be quite severe. Carbon dioxide retention does not

occur as a rule because of compensatory hyperventilation. Excessive venous admixture, however, in association with other forms of alveolo-respiratory insufficiency as well as ventilatory insufficiency, plays an important role in the development of the symptoms, signs and physiologic manifestations in chronic pulmonary emphysema, to be discussed in more detail below.

(c) *Reduction in Oxygen Diffusing Capacity.*—This is observed as the main defect in a variety of diseases, e.g., pulmonary scleroderma, pulmonary granulomata of varying etiologies, and miliary infiltrations of the lungs secondary to metastatic carcinoma and to hematogenous tuberculosis. The pattern of dysfunction resulting from this abnormality is one of hyperventilation in all stages of activity, arterial anoxia on exercise, and dyspnea. That anoxia does not occur at rest until late in the course of the disease is not surprising since a reduction in diffusing capacity for oxygen is quite compatible with full saturation of the arterial blood, provided the quantity of oxygen to be transported across the alveolo-capillary membrane is not large. Ventilatory capacity is maintained at normal levels as a rule; hence the exertional dyspnea of which these patients complain is due to a reduction in breathing reserve induced by hyperventilation. Resting hyperventilation is probably due both to proprioceptive reflex stimuli originating in the lungs and to the increase in the sensitivity of the medullary center to the carbon dioxide stimulus, just as in the cases of pulmonary fibrosis mentioned previously. Hyperventilation during exercise is, however, augmented by the effect of reduced arterial oxygen tension upon chemoreflex drive.

### Combined Ventilatory and Alveolo-respiratory Insufficiency

It is less common in practice to find these more or less "pure" patterns of dysfunction as outlined above than it is to find combined forms. For example, while silicosis results chiefly in ventilatory insufficiency, it is not infrequent to find certain patients without complicating emphysema who exhibit varying degrees of impaired gas exchange. Increased dead space ventilation and increased venous admixture, when they are present, however, are rarely of sufficient magnitude to result in significant arterial anoxia and practically never bring about carbon dioxide retention. Reduction in oxygen diffusing capacity also is seldom of such magnitude as to produce signs or symptoms.

The best illustrations of combined ventilatory and alveolo-respiratory insufficiency is that provided by chronic pulmonary emphysema. The patterns of dysfunction observed in this disease range from simple reduction in ventilatory capacity, with mild dyspnea on exertion as the only symptom, all the way to severe arterial anoxia, carbon dioxide retention, dyspnea at rest, and breakdown of the mechanism regulating ventilation. A detailed account of the patho-physiologic aspects of chronic pulmonary emphysema is beyond the scope of this chapter but certain essential features should be pointed out. Ventilatory insufficiency in emphysema is chiefly the result of decreased ventilatory capacity, the compensatory hyperventilation which is frequently observed being of relatively minor importance. Alveolo-respiratory insufficiency results from increased dead space ventilation and venous admixture as well as decreased oxygen diffusing capacity.

The most important feature of emphysema, however, which sets it apart from the other chronic pumonary diseases, is the great reduction in ventilatory capacity which occurs together with disturbance in gas exchange. Because of this the only physiologic means of combatting the effects of disturbed gas exchange, i.e., compensatory hyperventilation, is often lost to the emphysematous patient when it is needed most. This is illustrated in the development of that stage of the disease characterized by breakdown of the mechanism regulating ventilation. As previously mentioned, in certain emphysematous patients with severe arterial anoxia and high arterial carbon dioxide tension, the major stimulus to ventilation is no longer derived from the medullary center but rather originates in the chemoreceptors of the aortic and carotid bodies under the stimulus of arterial anoxia. This stage of the disease is reached as follows.

When ventilatory capacity is no longer adequate to maintain sufficient compensa-

tory hyperventilation progressive carbon dioxide retention develops and this if sustained, is always associated with an increase in the amount of blood bicarbonate This increase in alkaline reserve leads to a reduction in the sensitivity of the medullary

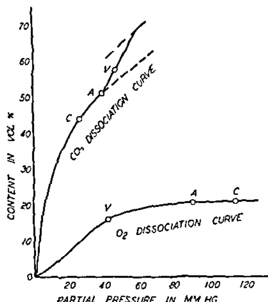

Fig 149 —Representative physiologic dissociation curves of whole blood for carbon dioxide and oxygen drawn to the same scale — — — represents the $CO_2$ curve for fully arterialized blood — — represents the $CO_2$ curve for fully reduced blood V = values for mixed venous blood A = values for mixed arterial blood and C = values for capillary blood derived from hyperventilated alveoli normally perfused

The effects of hyperventilation of normal alveoli upon carbon dioxide excretion and arterial oxygen saturation are apparent from inspection of these curves Reduction in $CO_2$ partial pressure in the blood by hyperventilation results in a significant reduction in $CO_2$ content whereas elevation in $O_2$ partial pressure by hyperventilation will result in only negligible elevation of oxygen content and saturation of the blood

center to the carbon dioxide stimulus a consequent decrease in centrogenic drive to ventilation and more carbon dioxide retention As the vicious cycle thus started progresses centrogenic drive diminishes further and chemoreflex drive increases in importance until finally it becomes dominant When this occurs hyperventilation is usually *no longer observed even if the total* breathing reserve has not been called upon anoxia and gaseous acidosis are intense polycythemia is present as a rule and right heart failure is common The precise reason for the failure of anoxia to induce hyperventilation in these circumstances is not entirely clear Although it might be postulated that prolonged dependency upon the chemoreflex drive which in normal man seems to be a mechanism for temporary activity might result in diminution of its strength this has not yet been shown to be true

*Conclusion* —From this brief introductory discussion it is clear that although the over all function of the lungs can be dissected for purposes of discussion into three main components *viz* ventilation gas exchange and regulation of ventilation these factors are markedly influenced by one another Analysis of pulmonary dysfunction therefore in subacute and chronic pulmonary disease must necessarily be based upon an interpretation of all the factors involved Only in this manner can a clear understanding of the nature of pulmonary dysfunction be reached and rational therapy instituted

# DISEASES OF THE LUNGS

By J WINTHROP PEABODY M D and J WINTHROP PEABODY JR M D

## PULMONARY CONGESTION AND EDEMA

### PULMONARY CONGESTION

Congestion of the lungs follows acute inflammatory lesions such as those caused by pneumonia respiratory obstruction and over rapid expansion of a collapsed lung or it may follow acute circulatory failure caused by left ventricle failure congenital heart disease mitral stenosis, or systemic diseases associated with fluid retention in the lungs or other organs It may be difficult to determine whether the severe dyspnea is due to a primary pulmonary inflammation or to congestion from cardiac disease If a few days of rest and the use of mercurial diuretics fail to alleviate the symptoms, pulmonary insufficiency may be considered the cause Measurement of circulation time is diagnostic in cardiac studies for the velocity of circulation is not impeded in uncomplicated pulmonary congestion However both pulmonary and cardiac insufficiency may be coexistent particularly in ventricular failure

*Acute congestion* (hyperemia) of the lungs may follow inhalation of a foreign body or irritating gases shock infections, trauma and vascular and hemorrhagic diseases It may last for a few minutes or for several hours It becomes severe when transudates fill the alveoli The circulation in the affected area is slowed down fluid floods the lung reabsorption is interfered with and edema develops The prognosis is grave A collateral hyperemia sometimes occurs when a lung obstruction is present or as the result of a rapidly developing pleural effusion, a spreading pneumonia or a pneumothorax

*Chronic passive congestion* follows any obstruction to free flow of blood from the lungs to the heart whether this is due to cardiac vascular pulmonary or extrapulmonary disease The most frequent causes are hypertensive heart disease and rheumatic mitral valvulitis aortic regurgitation stenosis and myocardial infarction Obstruction to pulmonary circulation may also arise from pulmonary diseases such as hypertrophic pulmonary emphysema fibrosis sclerosis atelectasis pneumoconiosis chronic abscesses bronchiectasis and tumor

*Hypostatic passive pulmonary congestion* occurs in the lower posterior area of the lungs in patients with prolonged infections cerebral apoplexy in elderly patients long confined to bed and in those in prolonged coma It may also occur in any chronic state causing interference with respiration Such interference resulting in stagnation of blood

in the dependent areas of the lungs is therefore unlike a mechanical congestion. In a prolonged hypostatic congestion resistance of the lung to infection decreases and a low-grade pneumonia may develop. To prevent this condition Cecil advises deep-breathing exercises for the asthenic or debilitated patient, changing the patient's position in bed or having him sit up in a chair, and improving his morale by use of psychotherapy, physiotherapy, and proper diet.

Pulmonary congestion leads to edema when the serous fluid of the capillaries escapes into the parenchyma and bronchial tree and involves one or both lungs.

## Pulmonary Edema

*Etiology.*—Pulmonary edema and anoxia are so closely associated that it is difficult to determine which precedes the other; severe anoxia may cause pulmonary edema; pulmonary edema may cause or aggravate anoxia. The edema may result from left-ventricular failure secondary to disease of *the coronary artery, arterial hypertension,* aortic stenosis or insufficiency, or mitral disease; from congenital heart disease; from pulmonary diseases associated with capillary damage or hemodynamic alterations in the lung produced by obstructive emphysema, gaseous irritants, pulmonary infarction, or polycythemia vera; or from systemic diseases associated with fluid retention in the lung or other organs. Acute pulmonary edema may be a complication of acute infectious disease, poisoning by various substances or asphyxiating gases, or disease of the central nervous system (such as cerebral trauma, myelitis, or cerebral embolism or thrombosis) and commonly follows shock.

*Pathogenesis.*—Edema is produced by imbalance between the osmotic pressure of the plasma proteins and the capillary blood pressure. The capillaries, unlike the venous and arterial vessels, do not form a continuous channel but rather a network providing a safety valve to prevent undue increases of pressure. This balance of pressure is never quite perfect, being always just at the edge of fairly free protein leakage. When dyspnea is present, the negative intrapleural pressure is much increased, particularly if the respiratory passage is restricted by some exudation. However, if the circulation remains adequate, a certain degree of anoxia can be withstood normally, without causing edema.

The thin alveolar membrane and the delicate capillary endothelium are all that separate blood from air in the lung tissues and are the only barrier to transudation of fluid from the blood vessels into the tracheobronchial tree. Any affection tending to increase the pressure within the capillaries or to decrease the pressure within the air channels will in turn increase the transudation through the intervening membrane. Although the permeability of the capillary walls is increased by anoxia, with further leakage of protein and water into the pulmonary tissue, if the circulation remains fairly good, the lymphatic system can successfully remove the leakage before the fluid penetrates the alveolar walls and invades the air spaces. On the other hand, when the circulation is impaired, fluid in the alveolar walls passes directly into the alveolar air *spaces and exerts mechanical impediment* to the passage of water to the capillaries, and anoxia begets anoxia.

With mechanical obstruction to the alveoli from seepage of fluid into the airway and resultant interference with free circulation of air, the lung solidifies. The interstitial structures thicken, and loss of elasticity in the pulmonary tissues prevents free expansion and contraction of the lung. This in turn leads to impairment of the normal physiologic mechanism controlling the rate and depth of respiration. Rapid or shallow breathing causes incomplete aeration and anoxia, and the resultant pulmonary edema causes a reduction in the oxygen saturation of the arterial blood and so increases the anoxia.

*Clinical Features.*—In pulmonary edema a variable degree of dyspnea is noted initially together with hacking cough and pinkish sputum. Cheyne-Stokes respiration and cyanosis are noted in advanced cases. In cases of left ventricular failure attacks of paroxysmal dyspnea occur with cough and wheezing ("cardiac asthma"). Roentgenologic findings in pulmonary edema vary depending on the acuteness or chronicity of

the condition and on associated pulmonary affections

*Treatment* —Medical treatment includes rest warmth, reduction of fluid intake, the use of digitalis mercurial diuretics, sedation, and venesection *Oxygen therapy is of* the greatest importance and should be administered before the occurrence of serious respiratory and circulatory decompensation When given after dyspnea cyanosis and moist rales develop oxygen may not prevent irreversible pulmonary edema (When pulmonary edema is associated with pneumonia 50 cc of 50 per cent glucose injected intravenously for 2 or 3 days at intervals of from 8 to 12 hours may be of value ) Venesection 250 to 500 cc is favored by most authors unless there is shock The use of aminophylline, 0 24 Gm by slow intravenous administration is recommended Morphine sulfate in 15 mg (1/4 grain) doses is proposed for lowering the excitability of the nervous system except in cases of collapse

## PULMONARY HEMORRHAGE

Hemorrhage of the lung a common symptom in pulmonary disease may result in only occasional streaking of the sputum or may be (1) intermittent bleeding which if continued may lead to blockage of the bronchial tree, atelectasis and exsanguination or (2) fatal massive hemorrhage from the rupture of a blood vessel

During hemorrhage the blood may escape into a bronchus or a pulmonary cavity and be expectorated in the liquid state or it may be temporarily retained and expectorated *later in clots* On the other hand, the blood may pass into the alveolar *or interstitial* tissues or may rupture the capillary walls and be expectorated as reddish or brownish sputum When less than 4 cc are expectorated, the term hemoptysis is used rather *than hemorrhage*

Profuse hemorrhage occurs more often in chronic than in acute pulmonary disease Hemorrhage occurs about equally in both lungs and equally in all lobes, sometimes it is bilateral The bronchi and any rigid cavity crossed by thrombosed blood vessels are the usual sources of the bleeding Bleeding may result from pulmonary diseases such as bronchial ulceration or compression tuberculosis, bronchial carcinoma bronchiectasis and pulmonary abscess Other occasional causes of pulmonary hemorrhage are blood dyscrasias vitamin deficiencies altering the structure of the blood vessels foreign bodies, trauma, cardiac diseases associated with mitral stenosis hypertension and arteriosclerosis, pneumonia and bronchial adenoma

*The symptoms attending hemorrhage* are those of the underlying disease in 90 per cent of cases

*Treatment* —Slight hemoptysis requires no attention except determination of the underlying cause Efforts must be made to allay the patient s alarm if the bleeding is profuse Sedatives may be administered but strong opiates particularly morphine which may interfere with cough reflex and depress the respiratory center should be withheld Bed rest is essential The head should be propped up with pillows to facilitate free breathing and expectoration If the bleeding is profuse intravenous injection of 10 per cent calcium gluconate solution has been recommended Pneumothorax may be used if the site of bleeding can be determined

Blood transfusion is indicated for severe loss of blood Usually medical treatment is of no avail The hemorrhage may stop spontaneously

## PULMONARY EMBOLISM AND INFARCTION

*Incidence* — About 6 per cent of all post operative deaths are due to pulmonary embolism (Barnes) and the incidence is increasing annually This may be due to the increasing number of older patients with cardiovascular degenerative processes promoting thrombosis and embolism to the increasing number of older persons having major operations and to the steadily increasing number of accidents leading to long confinement in bed and immobility of the limbs Thromboembolism occurs equally in both sexes

*Etiology* —Prolonged bed rest is one of the chief causes of pulmonary embolism since it favors the development of phlebothrombosis But thrombi in the right ventricle or in the right auricle or thrombi from vegetations on the valves of the right side of the heart may also cause such embolism Moran has found pulmonary embolism a frequent complication of tuberculosis

*Clinical Features* —When a blood clot is dislodged from its point of origin it is carried to the lungs by way of the heart and if large may lodge in the pulmonary artery and cause sudden death by obstructing the flow of blood through the lung and producing heart failure If the embolus is small it may block a smaller blood vessel or may split into small emboli which reach the terminal ramifications

When the embolus is massive the patient is seized with severe pain in the chest and extreme dyspnea become blue in the face, and dies within a few minutes

The general symptoms are rise in temperature and pulse rate and in the few nonfatal cases dyspnea perspiration paleness lowered blood pressure and an apprehensive appearance Cough and hemoptysis may occur Pleuritic pain with exaggerated dyspnea is a common symptom of a small pulmonary embolus pleural effusion follows a few hours later These symptoms particularly after a major operation suggest embolism These early symptoms often imitate those of primary cardiac disease differentiation is sometimes made by electrocardiographic studies

Pulmonary infarction almost always occurs as a result of sudden occlusion of a branch of the pulmonary artery The symptoms depend on the size of the occluded blood vessel the status of the pulmonary circulation the degree of restriction of blood flow through the lungs and the number of emboli The symptoms are dyspnea cyanosis apprehension and some degree of shock with chest pain fever cough and hemoptysis Sometimes the lung on percussion sounds dull or flat auscultation sometimes discloses a friction rub or rales Pleural effusion at times hemorrhagic is occasionally found

*Radiologic Findings* —The characteristic radiologic finding of pulmonary infarction is a wedge shaped homogenous density As healing occurs the density become smaller and presents a transverse linear appearance often confused with plate like atelectasis pleurisy or postoperative pneumonia

*Treatment* —Treatment is almost entirely preventive The physiologic cause of the pulmonary embolism is a disproportion between prothrombin and antithrombin in the blood A clot may occur even when the prothrombin level is low if the antithrombin content is proportionally lower Following tissue injury of whatever cause the antithrombin content of the blood is diminished and this may bring about a disproportion between prothrombin and antithrombin sufficient to produce a thrombosis if the antithrombin level does not return to normal within a few days For this reason prophylactic anticoagulants are rather widely used in cases in which a thrombosis may be anticipated The use of these agents is also indicated for treatment of pulmonary embolism and infarction (*See* Chapter 24 )

Barnes A R Problem of Pulmonary Embolism West J Surg 1942 *50* 551

*the condition and on associated pulmonary* affections

*Treatment* —Medical treatment includes rest warmth reduction of fluid intake, the use of digitalis mercurial diuretics sedation and venesection Oxygen therapy is of the greatest importance and should be administered before the occurrence of serious respiratory and circulatory decompensation When given after dyspnea cyanosis and moist rales develop oxygen may not prevent irreversible pulmonary edema (When pulmonary edema is associated with pneumonia, 50 cc of 50 per cent glucose injected intravenously for 2 or 3 days at *intervals of from 8 to 12 hours* may be of value) Venesection 250 to 500 cc is favored by most authors unless there is shock The use of aminophylline 0 24 Gm by slow intravenous administration is recommended Morphine sulfate in 15 mg (¼ grain) doses is proposed for lowering the excitability of the nervous system except in cases of collapse

largement of the heart or by pressure on the base of the lung by abdominal growths subdiaphragmatic abscess or ascites In pleural effusion and in pneumothorax the uniform collapse producing symptoms is due to reduction of the aerating surface and to mediastinal displacement and cardiac embarrassment

Although the shrunken portion of the lung may exist for many years without impairment of pulmonary function and suddenly re-expand the retracted bronchial tree may become permanently distorted and this may result in defective drainage stagnation and ultimate infection The process then becomes irreversible and fibrosis and bronchiectasis develop

*Obstructive atelectasis* occurs in many intrathoracic affections in which bronchial obstruction is a common factor (*See* page 879)

As a result of the secretion and caseous material in their bronchi constriction of the bronchi due to endobronchial tuberculosis and fibrosis and the pressure caused by lymph nodes and tuberculomata, as well as the compression of pulmonary tissue by collapse therapy, tuberculous patients are particularly predisposed to atelectasis

Massive collapse occurs when there is a gross bronchial obstruction with paralysis of the muscles as in diphtheria Postoperatively or in case of trauma to the chest acute massive atelectasis may occur Massive atelectasis may also follow any sudden obstruction of the bronchi pulmonary infarction infection and allergic attacks

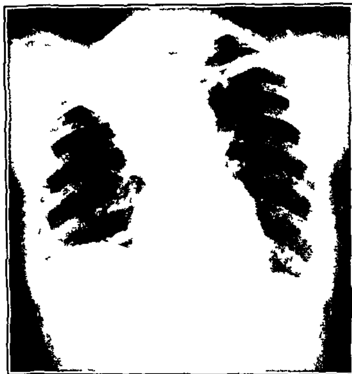

FIG 1?0 —Atelectasis in right upper lobe with endobronchial disease

Complete obstruction followed by absorption of gases and maximum retraction of the involved area usually occurs within a few hours if however there has been previous inflammation of lung tissue in the affected area the gas absorption is less marked and the retraction occurs more slowly The collateral circulation of gases may partially maintain the inflation of the lung if the bronchial obstruction is not extensive

Postoperative atelectasis may follow any operation which causes interference with

## PULMONARY ARTERIOSCLEROSIS

*Etiology* —Pulmonary arteriosclerosis is a rare disease that may be either a manifestation of a generalized arteriosclerosis of the entire vascular system or a consequence of hypertension of the lesser circulation The disease may be primary without preceding lung or heart disease (Ayerza s disease), or secondary attendant upon some long standing condition such as bronchiectasis pneumoconiosis tuberculosis congenital cardiac or thoracic abnormality cardiovascular disease emphysema or asthma When the disease is primary there is arterio-capillary fibrosis of the lung with obliteration and angutis of the smaller arterioles when the disease is secondary there is a widespread sclerosis of the larger branches of the pulmonary artery

*Clinical Features* —Usually the patient reports having had a cough with mucopurulent expectoration over a period of years dyspnea on exertion and recurrent attacks of bronchitis Headache somnolence hemoptysis and precordial pain may be noted As the disease progresses edema is indicative of a right-ventricular failure and increased venous pressure with dilatation and hypertrophy of the right side of the heart and of the superficial veins is apparent Cyanosis is usually marked the patient s hands and face becoming almost black (Black cardiac) The fingers may show definite clubbing Other pathologic changes include enlargement of the liver lowered renal function and infarction of the lungs Radiologic studies often reveal prominence of the pulmonary conus and artery and enlargement of the right ventricle Oblique views afford better demonstration hypertrophy of the body of the right ventricle being demonstrated in the left anterior view and enlargement of the outflow tract and conus in the right anterior view Pulmonary arteriosclerosis may be differentiated from polycythemia vera by its respiratory symptoms, absence of any splenic enlargement, and signs of general passive congestion The condition may endure for many years Death often results from myocardial failure or from an intercurrent infection

*Treatment* — Treatment consists in symptomatic relief, attempts to relieve the underlying causes, which are often not amenable to therapy, and the management of congestive heart failure by the usual means of rest diet oxygen digitalis, and diuretics The prognosis in this type of heart failure is considerably worse than in general heart failure

## ATELECTASIS

*Definition* — Atelectasis is incomplete expansion of the lung It occurs when an air passage is completely or almost completely occluded and non aeration of the alveoli of some unit of the lung which has no collateral respiration through communication with some other air passage results

*Types of Atelectasis* —Three types of atelectasis are recognized congenital compressive and obstructive

Congenital atelectasis is caused by absence of alveoli mechanical obstruction of the bronchi by amniotic fluid or inflammatory processes that prevent complete unfolding of alveolar tissues Such atelectasis may cause death at birth or if the occlusion is minor produce a blue baby Recovery may be spontaneous or may require artificial aspiration of the occluding fluid or mucus Unless the occluded areas become infected compensating areas may prevent development of symptoms and the growing child may recover without diagnosis of the condition If atelectasis continues bronchiectasis may develop

*Compressive or adjustment atelectasis* is due to pulmonary retraction where the peripheral support of the lung is inadequate or there is reduction of the thoracic volume The pressure may be produced by thoracic deformities by pericardial effusion by en

fected pulmonary areas are already over-functioning

When the breathing is shallow and cyanosis and dyspnea are present inhalation of 50 to 70 per cent oxygen may be required to maintain respiratory function This may be administered by oxygen tent oxygen mask or nasal catheter Catheter suction to evacuate the exudates has been recommended If this cannot be instituted or is ineffective bronchoscopic aspiration should be attempted Penicillin or some other antibiotic should be introduced into the bronchial tree after the evacuation of the exudates

It must be remembered that these measures may not be required in simple or lobular atelectasis as these cases often clear up spontaneously the physical postoperative measures already described may suffice

Treatment of atelectasis other than postoperative is that of the primary disease

## EMPHYSEMA

*Definition* —Pulmonary emphysema is a disease in which there is an interference with the normal functioning of respiration and circulation with subsequent dilatation and rupture of the alveoli and decreased elasticity of the involved lung Five general types are recognized (1) obstructive or hypertrophic emphysema (2) compensatory emphysema (3) senile or atrophic emphysema (4) interstitial emphysema and (5) progressive bullous emphysema The *chronic* or hypertrophic type is generally meant when emphysema of the lung is discussed

Although the disease has been reported in infants only three weeks old it occurs most often in males of middle age or over who have a history of chronic respiratory obstruction following asthma chronic bronchitis chronic cough from tuberculosis bronchiectasis or pneumoconiosis The disease may occur suddenly in an apparently healthy person who several months before recovered from an atypical pneumonitis or bronchial asthma

*Etiology and Pathogenesis* —The chief etiologic factor in emphysema is chronic interference with the free passage of air in the bronchi

It is generally agreed that loss of elasticity in the pulmonary tissues either by infection or atrophy is the chief factor in disturbance in respiratory function in this disease

With loss of elasticity, the air sacs are distended Bullæ appear on the surface of the lung as the superficial air sacs are stretched to a greater extent than those situated deep in the lung since the greatest expansion is at the surface of the lung With increased stretching of the alveolar walls the air sacs are joined the walls themselves torn and the pulmonary capillaries destroyed so that large areas have a diminished circulation of blood Moreover a negative pressure within the chest normally facilitates the return flow of venous blood to the heart in emphysema the negative pressure is lost through inelasticity of the structures and the pressure may even be positive during expiration thereby impeding the return flow of blood and bringing about an elevation of venous pressure If the pressure is sufficiently great the air may be forced into the subcutaneous tissues or into the pleural cavity and produce a pneumothorax that is if alveoli or blebs are ruptured

Another effect of reduced elasticity is interference with the exchange of gases in the lungs another is an increased amount of residual air which keeps the alveoli distended The residual air accumulates at the expense of vital capacity which may be diminished to less than half of normal The decreased vital capacity may approximate the resting tidal air so that the

pulmonary drainage Sedation, suppression of cough and expectoration because of pain, fixation of the diaphragm and keeping the patient long in one position cause stagnation secretions of the upper respiratory tract are added to pulmonary secretions Postoperative atelectasis may involve an entire lung a single lobe or only part of a lobe

*Clinical Features* —The manifest symptoms of atelectasis are usually those of the primary disease Except for a rapid pulse postoperative atelectasis is often symptomless and without *x* ray examination will not be suspected When two or three days after operation a patient has difficulty in raising sputum shows a slight increase in temperature and exhibits poor aeration of the lower lobe together with coarse rales at the bases atelectasis should be considered In severe cases there may be high fever prostration distressing cough chest pain, dyspnea and tachycardia suggestive of lobar pneumonia except that the heart is displaced to the affected side and the sputum is seldom bloody The affected side of the thorax may be found to be immobile and the breath sounds may be diminished or absent

Usually collapse occurs in the lower areas of the lungs Diminished or absent breath sounds are noted over those regions with lessening of the normal resonance on percussion and fine crackling rales during inspiration Displacement of the heart toward the affected side will be noted

Radiologic findings vary according to the extent of the atelectasis The opacity is dense and covers a large area in gross collapse the heart trachea and mediastinum are displaced toward the affected side and the diaphragm is found to be elevated

*Differential Diagnosis* —Atelectasis is differentiated from pneumothorax and pleural effusion by the position of the heart and the mediastinum which in massive collapse are drawn toward the affected side they are displaced to the opposite side in pleural effusion and pneumothorax The presence of fever and the physical signs of atelectasis may suggest pneumonia but the displacement of the heart, mediastinum, and diaphragm will rule out pneumonia Pulmonary embolism may be suspected but hemoptysis is absent in atelectasis, and shock and pain are less severe

*Prognosis* —The prognosis in atelectasis is generally good the condition disappearing in a few days unless the primary affection is serious or chronic In such cases, and in those in which pneumonia or abscess develops the atelectasis may become bilateral and persistent

*Treatment* —Treatment of postoperative atelectasis is preventive Every effort must be made to prevent accumulation of secretion in the bronchial tree Movements of the diaphragm and lower ribs must not be restricted and the cough reflex must not be inhibited

Operations should be postponed if possible when infection of the upper respiratory tract is present Patients with chronic bronchitis are best operated on during the summer Elderly and feeble patients should be encouraged to walk about for several weeks before operation

At operation, the patient should be placed in a position to facilitate drainage The anesthesia should be as light as possible During the operation the upper air passage should be kept free from excessive secretion by frequent aspiration with a rubber catheter

Postoperative therapy is directed to removal of accumulated secretions and keeping the air passages clear Using the Trendelenberg position turning the patient from side to side at intervals, encouraging deep breathing and expectoration avoidance of tight bandaging and early ambulation are all suggested measures

Inhalation of a mixture of 5 per cent carbon dioxide and 95 per cent oxygen at intervals of from 2 to 4 minutes is recommended to expand the bronchial walls and stimulate the cough reflex Oxygen alone tends to increase the viscosity of the secretions causing them to adhere to the bronchial membranes Inhalation of steam has been found to overcome the disadvantages of the oxygen in the carbon dioxide mixture steam inhalation is also more effective in liquefying the exudate than the ordinary expectorants When symptoms of respiratory distress are marked stimulation of respiration by carbon dioxide is contraindicated since the unaf

compensates for impaired function of another segment Increase in the size of the alveoli does not necessarily increase their function and their permanent distention tends to impair the thoracic bellows although in some instances readjustment may occur without pathologic emphysema In unilateral compensatory emphysema the emphysematous side will appear more prominent and mobile vocal fremitus will be relatively small the position of the diaphragm and its mobility are relatively normal In senile emphysema the activity of the abdomen is greater than that of the chest wall

*Interstitial emphysema* develops upon rupture of the marginal alveoli by trauma or by violent coughing The air either passes into the subpleural space or the peribronchial or perivascular tissues or passes along the

Fig 151 —Emphysema in upper left lobe

diminished hyperresonance will be noted and breath sounds exaggerated

*Senile atrophic or postural emphysema* is a disease of old age The distention is generally considered due to stiffness of the spine rather than to loss of elasticity The lung tissue is wasted the ribs become more horizontal as the vertebral bodies become fixed and with degeneration of the disks the thoracic spine becomes kyphotic so that the chest assumes a barrel shape It is a nonobstructive emphysema the lungs are

pleura and enters the mediastinum from which it travels along the trachea to invade the subcutaneous tissues of the neck Mediastinal emphysema is more apt to result from rupture of pulmonary alveoli after operations on the neck than from direct aspiration of air into the mediastinum Postmortem examination has shown extensive subcutaneous emphysema over the front of the chest with the air bubbles arranged like a string of pearls and the heart

patient although comfortable in bed will be dyspneic upon the slightest exertion In this case the alveolar air and the arterial blood contain more carbon dioxide and less oxygen than is normal the saturation of oxygen in the blood sometimes becoming as low as 60 per cent, which would cause a normal person to become unconscious whereas the emphysematous patient may show no ill effects Impairment of carbon dioxide elimination is considered due not only to inability of the patient to increase pulmonary ventilation but also to the unequal ventilation of the lung much of the inspired air being wasted in ventilating the superficial alveoli which have become overstretched avascular, and relatively functionless

*Symptoms and Signs* —The symptoms may arise suddenly in infancy or have an *insidious onset in later life* The most constant symptom is shortness of breath often accompanied by cyanosis of a severity that the physical signs do not seem to justify Cyanosis is due to the inability to aerate the blood but *compensatory polycythemia* is also a contributing factor

Most patients have a chronic cough Expiration is prolonged sometimes being four times the length of inspiration However this sign is not pathognomonic of emphysema as it is frequently noted in men of middle age or over The barrel shaped chest of the patient is a characteristic sign The ribs are elevated and tend to lie horizontally the costal angle is increased the chest is elevated and its expansion restricted Hyperresonance is noted on percussion chest expansion is decreased breath sounds are weak heart sounds are soft and distant and vocal fremitus is diminished

An increased carbon dioxide level in the blood may be demonstrated Measurements show the vital capacity is diminished

Radiologic examination may show characteristic changes in the lungs but these are not always present *Increased aeration* may be noted unless there is considerable fibrosis The diaphragm appears depressed flattened and restricted in motion Translucency of the lung is increased and the hilar shadows are accentuated Blebs or bullae may cast annular transparencies and resemble tuberculous cavitations

*Treatment* —Treatment of emphysema is entirely symptomatic, since neither elasticity of the tissues nor the structure of the chest can be restored The disease is usually slowly progressive and, because of its associated bronchitis may become disabling Since it is incurable the patient must follow a careful regime of rest diet, and exercise avoid exposure to sudden changes in temperature and keep within his physical limitations It is important that concurrent diseases such as bronchitis and asthma be treated Bronchial spasm may be relieved and dyspnea therefore lessened by administration of ephedrine in doses of ⅜ to ¾ grains Aminophylline 0 5 gram in rectal suppositories has been recommended Nebulized epinephrine may lessen purulent expectoration Inhalation of oxygen alone is helpful *during dyspneic attacks the dyspnea being* due to difficulty in transmitting oxygen to the arterial blood not to impairment of carbon dioxide elimination Continuous inhalation of 50 per cent oxygen sometimes *brings progressive or complete relief* of dyspnea, if the patient can continue in the oxygen-enriched atmosphere for a period of from 2 days to 1 week Patients with associated pulmonary fibrosis may be helped by this treatment but require continued oxygen at home Barach recommends inhalation of 100 per cent pure oxygen in a mask for 20 or 30 minutes daily in these cases Intermittent positive pressure breathing (I P P B ) according to the method of Motley *et al* may afford symptomatic relief in emphysema

Use of an abdominal belt has been recommended especially in patients with sufficient adipose tissues to increase intra abdominal pressure by elevating and supporting the diaphragm Respiratory exercises to teach patients to deflate the lungs and increase the use of the diaphragm is sometimes advocated

*Pneumoperitoneum* which has been extensively used in treatment of tuberculosis is receiving favor in therapy of emphysema

## OTHER TYPES OF PULMONARY EMPHYSEMA

*Compensatory emphysema* is a condition in which dilatation of one part of the lung

The walls of the acute abscess are soft and friable, those of the chronic abscess are fibrous and smooth. Lung abscesses may increase by direct extension or by a spreading of the infective material through neighboring bronchi. When the protective wall of the abscess breaks down and becomes necrotic the inflammatory process extends to the surface of the lung and causes an empyema or a gangrenous pneumonia.

*Symptoms.*—The symptoms of lung abscess vary according to the site and stage of the disease and the degree of bronchiectasis and consolidation in surrounding tissue. The first manifestations may be chills with fever followed by coughing and expectoration. If the onset of the disease is sudden there may be profuse sweating and prostration. The cough increases with progress of the abscess, and expectoration of a large quantity of foul sputum indicates rupture of the abscess into a bronchial ramification—the only true pathognomonic symptom. Periodically, the sputum may be streaked with blood. Pleuritic pain may occur in the initial stage of the disease. Sepsis is demonstrated by a high sedimentation rate and a leukocytosis. In cases with a slow onset there may be a secondary anemia and hypoproteinemia. Some patients with chronic lung abscess suffer from general malaise, aching of the musculature, and loss of both weight and strength. Cyanosis and clubbing of the digits may develop suddenly.

*Diagnosis.*—No signs are revealed on palpation if the lung abscess is small and deeply located. Increased tactile fremitus may be noted if the abscess is large and the adjacent tissues are extensively inflamed; the fremitus may be decreased or absent if pleuritic exudates are present. Chronic cases show decreased movements of the thorax and atrophy of the chest muscles. The percussion note is variable; over large abscesses there may be bronchial breathing.

Roentgen findings depend on the extent of the inflammatory process. The roentgenologic findings in general are typical of many other pulmonary infections. In the early stages small areas of infiltration may be revealed which remain rather clearly demarcated even when the area increases and becomes denser. A definite fluid level is often observed.

The bronchogram is of value in distinguishing between an abscess and a bronchiectasis. Bronchoscopy may demonstrate the location of the abscess, by indicating from which bronchus pus is exuding, and may also give evidence of obstruction. Bronchoscopy is used to remove tissue for determination of malignancy.

Lung abscess must be differentiated from empyema rupturing into a bronchus, bronchiectasis, cystic disease of the lung, pulmonary tuberculosis, cancer of the lung, and fungus disease.

*Treatment.*—Poor results in treatment have generally been due to late diagnosis and too conservative therapy. Medical treatment includes postural drainage, chemotherapy including the use of antibiotics, and bronchoscopic aspiration. Surgical therapy includes lobectomy or segmental resection and, in severe cases, pneumonectomy. Drainage by pneumonotomy or pleurotomy suffices in some cases.

Conservative treatment includes rest in bed and a nutritious diet, supportive therapy, and postural drainage. The use of aureomycin, streptomycin, or sulfadiazine to supplement penicillin may bring results comparable to those of early surgical drainage and make resection unnecessary. In acute abscesses aerosol therapy may be beneficial.

*Prognosis.*—Until the last decade prognosis in cases of pulmonary abscess was poor, the mortality rate being between 30 and 50 per cent. Greater use of lobectomy and pulmonary resection has resulted in fewer deaths.

Between 20 and 35 per cent of all lung abscess victims are said to have spontaneous recoveries.

*Preventive Treatment.*—Preventive measures are important in reducing the incidence of lung abscess. Since a predominating cause of pulmonary abscess is aspiration of infectious material, daily oral hygiene is important, as is special oral hygiene before the administration of any anesthetic. Local anesthesia is preferable for operations on the mouth or throat, since such anesthesia does not inhibit the cough reflex. Where general anesthesia is required, the patient's head

and large blood vessels surrounded by air bubbles

The symptomatology depends on the degree of circulatory embarrassment caused by pressure of the air bubbles on the vessel sheaths and the degree of respiratory impediment caused by the pressure of the air on the interstitial tissues Dyspnea and cyanosis may be observed, and retrosternal pain of short duration radiating to the neck and shoulders The symptoms may imitate those of pericarditis, pulmonary infarction, pneumonia or coronary thrombosis Unless subcutaneous emphysema is present, hyperresonance may be noted over the affected side on percussion with obliteration of cardiac dullness Crackling bubbling or crunching sounds (Hamman s sign) may be heard in the chest even without the aid of a stethoscope No therapy is required if the aberrant air in the interstitial tissues is small and unaccompanied by distressing symptoms Mediastinal pressure makes the condition serious Oxygen inhalation is recommended for dyspnea opiates for painful cough, and antibiotic therapy for secondary infections

*Bullous emphysema* a collection of distended vesicles forming large air pockets within the lung It may be a sequel to bronchial obstruction in childhood following bronchopneumonia, influenza or other acute infections, to aspiration of foreign bodies or to bronchiolitis from noxious gases It is frequently associated with fibrous tuberculosis, pneumoconiosis bronchogenic neoplasms and chronic pneumonitis Nonexpansile bullæ present no problem unless infection occurs or they are mistakenly diagnosed as spontaneous pneumothorax They may cause pressure on the surrounding tissues, may rupture or may cause recurrent pneumothoraces

No effective therapy has been devised and the prognosis is grave although some patients with the condition live for a number of years

## LUNG ABSCESS

*Definition* —A pulmonary abscess is an inflammatory process within the parenchyma of the lung in which there is some cavitation with free purulent fluid and necrosis Lung abscesses may be single or multiple and may involve either or both lungs Lung abscesses are called *simple* or *complex* according to the degree of involvement of the surrounding tissues and they may be acute or chronic, putrid or nonputrid

*Incidence* —These abscesses occur in persons of all ages, 50 per cent of the victims however are between 20 and 40 years old Such abscesses occur twice as frequently in men as in women Lung abscesses in children usually follow tonsillectomy or the inhalation of a foreign body The right lung is more frequently involved than the left and the lower lobe more often than an upper lobe

*Etiology* —Abscess of the lung is usually caused by the aspiration of infected material or by an embolism from some distant focus In many cases, pathogenic organisms in the mouth or upper respiratory tract are aspirated during an operation particularly during tonsillectomy dental operations and nose and throat surgery Lung abscesses may also follow bronchial obstruction pneumococcic pneumonia subphrenic abscess an infected hydatid cyst bronchiectasis extension of esophageal malignancy bronchiogenic carcinoma and fungous infections of the lungs They may also follow injuries of the chest impaction of infected material conveyed by missles Both aerobic and anaerobic organisms are present in most cases

*Pathology* —A lung abscess begins in the pulmonary parenchyma usually distal to an occluded bronchus

been fully determined Penicillin has proved less successful against these abscesses than against nonputrid abscesses

## PULMONARY CYSTS

*Pathogenesis* —Cysts of the lung are of two types congenital and acquired Congenital cysts are distinguished by the muscle cartilage and bronchial glands found in their walls and by their epithelial lining Some contend however that cysts found without the epithelial lining may nevertheless be true congenital cysts that have lost that lining through infection and that acquired cysts may become epithelialized as a result of the opening established between the cyst and the bronchus Still the usual opinion is that the epithelial lining usually columnar and sometimes ciliated distinguishes the congenital from the acquired type of lung cyst Congenital lung cysts are generally found in children soon after birth or early in infancy The cysts may be filled with air or fluid or both Some such cysts are symptomless and are discovered later in life during routine radiologic examination Acquired lung cysts unless parasitic in origin develop after pulmonary infection or mechanical dysfunction

*Symptoms* —Marked respiratory symptoms at birth that do not respond to the usual resuscitation methods should suggest congenital lung cyst Radiologic examination may reveal a balloon cyst producing mediastinal and diaphragmatic displacement Fluoroscopy and serial films will aid in the diagnosis

Both children and adults with congenital lung cysts usually have had from birth episodes of cough dyspnea and cyanosis with or without episodes of respiratory infection such as bronchitis whooping-cough or pneumonia Ballooning cysts may cause a spontaneous or tension pneumothorax by rupture into the pleural cavity Recurrent respiratory episodes are common fever tachycardia and dyspnea indicating the presence of infectious processes

*In some instances radiologic examination* alone will suffice for diagnosis

*Treatment* —Usually no treatment is required If dyspnea is present or sepsis occurs as a result of infection surgical removal *of the cyst is indicated*

*Prognosis* —The cysts are more serious in childhood because of their tendency to balloon and cause respiratory dysfunction Rubin believes that once the patient reaches maturity without mishap the condition remains innocuous unless infection arises

*Mediastinal cysts* are usually congenital filled with liquid and found around the pulmonary hilus the trachea the cardiac area the esophagus and the pericardium They may be confused with thymic tumors aneurysms neurogenic tumors or other solid mediastinal tumors

## TUBERCULOSIS

*Definition* —Tuberculosis is a widespread infective disease occurring in animals and man *It is caused by the tubercle bacillus* which may invade any part of the body, but usually invades the lung The disease

should be kept low to prevent aspiration into the trachea. When it is thought that a foreign body has been aspirated, bronchoscopic examination and removal of the foreign body, if found, follow at once.

Patients unconscious from alcohol, narcotics or trauma should have the head and neck kept low to prevent aspiration of infectious material. If an attack of pneumonia has not been properly resolved and there is wheezing or atelectasis, the patient should be examined bronchoscopically and any mucous plugs removed. These preventive measures, together with preoperative and postoperative use of antibiotics during internal surgery, should materially reduce the incidence of abscess of the lung.

## GANGRENE OF THE LUNG

*Definition.*—Gangrene of the lung (massive necrosis of the lung) and abscess of the lung are so closely related that it is difficult to distinguish sharply between them. But usually, pulmonary abscess is a localized lesion with rather sharp outlines and pulmonary gangrene a more diffuse condition without clear demarcation between the diseased and the healthy areas.

Gangrene of the lung, which usually affects one of the lower lung lobes, is a rapidly developing process characterized by massive destruction of pulmonary tissues, which become soft, pulpy and discolored. As the necrosis progresses, putrefactive liquefaction takes place; the fluid contains shreds of necrotic material and smells foul. The overlying pleura becomes intensely inflamed and the production of a putrid empyema or a pyopneumothorax is common.

*Etiology.*—Gangrenous suppuration of the lung may be a late sequel to bronchiectasis or a complication of bronchial obstruction caused by a tumor or a foreign body, or it may follow a lung hematoma arising from a severe contusion of the chest. Since Vincent's fusospirochetal organisms are frequently isolated from the necrotic tissue, some believe them of etiological significance. The general resistance of the body, the virulence of the invading organisms, and the degree of local vascular disturbance are all etiologic factors.

*Clinical Features.*—The most obvious features of gangrene of the lung are the extremely fetid breath and the putrid sputum, which often has a prune juice look. Hemorrhage is common and sometimes fatal. The symptoms are those of an acute toxic infection with remittent fever, chills, rapid pulse and prostration. Signs of an underlying disease such as bronchiectasis, aneurysm, or malignancy may also be present. The radiologic findings are suggestive of pneumonia, pulmonary abscess or, if the pleura is also involved, pleural effusion. Complications are uncommon because of the rapid progress of the disease.

*Complications.*—The usual complications of a gangrenous abscess are the spreading of the process into the pleura or the opposite lung and fatal hemorrhage. Occasionally an abscess of the brain may result from the lodgment of a septic embolus from the abscess. Such metastasis is made possible by the collateral circulation existing between the thoracic veins, the abdominal wall and the vertebral column, as described by Batson. The vertebral veins communicate with the intercostal veins, the abdominal veins and the azygos venous system. During cough the pressure in the pulmonary venous system is sufficient to send the blood into the collateral system.

*Treatment and Prognosis.*—The prognosis is generally poor. Only on rare occasions is the process subacute and chronic. Death may occur from one to three weeks after onset of the condition, particularly if the disease is apical.

*The only hope of cure, if the gangrenous process is not diffuse, lies in excision of the diseased area of the lung.* The role of the antimicrobial drugs in the treatment of gangrenous abscesses of the lung has not

until the patient becomes symptomless and the lungs radiologically clear. Streptomycin is indicated in all cases where symptoms seem to indicate a miliary tuberculosis without waiting for confirmation by discovery of tubercle bacilli in the sputum, for while the streptomycin is holding back the advance of the disease the general resistance of the patient can be built up for further protection. Many patients so treated tend to relapse as the organisms become resistant to the drug and in these death ensues.

The prognosis must be guarded. In some instances the disease is steadily progressive and fatal, the generalized tubercle formation causing an overwhelming toxicity. Use of the antibiotics in early cases may bring complete recovery. Continued therapy is indicated, since meningitis may develop many months after apparent recovery following streptomycin therapy.

*Acute pulmonary tuberculosis*, lobar or lobular in distribution, shows symptoms from onset, occurring in an apparently healthy person, and may be either caseous pneumonic or caseous bronchopneumonic in type. The onset and course of the infection resemble those of the pneumonias. *Acute lobar pneumonic tuberculosis* is an exudative process with symptoms resembling lobar pneumonia at onset. The rusty sputum and leucocytosis of the pneumonia, however, are usually absent and there is a greater remission of temperature than in pneumonia and there may be a slight hemoptysis. The

Fig. 152.—Miliary tuberculosis.

Administration as soon as the diagnosis is made of daily doses of streptomycin 2.0 Gm. intramuscularly is advocated for a period of from 4 to 6 months combined with complete bed rest. Others advocate administration of the drug for from 4 to 12 months with the addition of para-amino-salicylic acid to delay development of streptomycin resistance. Vitamin supplements and blood transfusion and other supportive measures should be used.

rarely absorbed or completely replaced by connective tissue, they may be held responsible for the chronic relapsing nature of tuberculosis. Nature tends to promote healing by segregating these foci from the adjoining tissues; to do this she produces a fibrous capsule with subsequent calcification. Whether the infection heals in this manner or progresses, breaks down, and leads to dissemination depends on the completeness of the immobilization of the tubercle bacilli.*

## CLINICAL FORMS OF PULMONARY TUBERCULOSIS

It is not always possible to classify a case of pulmonary tuberculosis as a particular type of the disease, but a number of general clinical forms may be recognized depending upon the extent, duration, accompanying symptoms, and particularly the pathogenesis of the lesion. The various ways in which reactivation of the primary process takes place has been described. The particular way in which this comes about determines the clinical form of the disease. When rupture into a blood vessel occurs with dissemination of foci throughout the lung, miliary tuberculosis develops. Rapid caseation, necrosis, and cavitation followed by rupture into a bronchus produce an acute pulmonary tuberculosis. A slowly advancing caseation of the process with continued infection leads to a chronic ulcerative tuberculosis, whereas a gradual transformation of a lobe or entire lung into a fibrous mass brings about a fibrotic tuberculosis.

*Miliary tuberculosis* results from a seeding of tubercle bacilli carried from an eroding caseous focus by the blood or the lymph to various parts of the body. In areas supplied with small capillaries the bacilli are filtered out and nodules form. Pancreas, stomach, thyroid, and brain are the least often affected. However, any organ or serous membrane may be infiltrated, but the lesions may be confined to one or both lungs or to one segment of one lung. The nodules, about 1 to 3 mm. in size, are found distributed within the parenchyma of the lung from apex to base, the tissues in between usually remaining clear of infection.

The disease arises most frequently in early childhood but may occur at any age. It is a complication of a small number of massive primary infections, usually developing within two years of their initiation. Miliary tuberculosis occurs not infrequently as a complication of a reinfection tuberculosis arising from a focus disseminating caseous material and spilling it into the blood stream. Myers states that it develops in approximately 1 per cent of all cases of chronic pulmonary tuberculosis. With further use of antibiotic therapy, miliary tuberculosis may occur less often.

In children, if the infection follows a primary lesion, the onset may be sudden with high fever, aching of the muscles, backache, and prostration. In adults the onset may be gradual with few symptoms, such as weakness and malaise, or no symptoms at all. In some cases even just before death x-ray evidence may be entirely lacking, but the diagnosis at this time may be suspected by positive ophthalmoscopic visualization of retinal tubercles and the recovery of tubercle bacilli from bone marrow aspiration. Early symptoms may be a gradual loss of weight and a persistent low grade fever; cough, if present, is mild and unproductive until the infection is well developed and then may be dry and irritating. These symptoms with enlargement of the spleen and distention of the abdomen may suggest typhoid fever, or the clinical manifestations may resemble those of bacterial endocarditis, sarcoidosis, or mycotic infections. The white-blood cell count may indicate a leukopenia or a leukocytosis, or if there should be a bone marrow involvement, a leukemoid reaction. Other symptoms noted may be due to the site of the infection or to the complications present in the affected organ.

Streptomycin therapy has been used successfully in checking the progress of the disease. Within a few days fever and toxicity may be abated and regression of the lesions may begin in a few weeks. In some instances this regression has continued

* National Tuberculosis Association 1950.

until the patient becomes symptomless and the lungs radiologically clear. Streptomycin is *indicated in all cases where symptoms* seem to indicate a miliary tuberculosis without waiting for confirmation by discovery of tubercle bacilli in the sputum, for while the streptomycin is holding back the advance *of the disease the general resistance of the* patient can be built up for further protection. Many patients so treated tend to relapse as the organisms become resistant to the drug and in these death ensues.

The prognosis must be guarded. In some instances the disease is steadily progressive *and fatal, the generalized tubercle formation* causing an overwhelming toxicity. Use of the antibiotics in early cases may bring complete recovery. Continued therapy is indicated since meningitis may develop *many months after apparent recovery* following streptomycin therapy.

*Acute pulmonary tuberculosis*, lobar or lobular in distribution, shows symptoms from onset, occurring in an apparently

FIG. 152.—Miliary tuberculosis.

Administration as soon as the diagnosis is *made of daily doses of streptomycin 2.0* Gm. intramuscularly is advocated for a period of from 4 to 6 months, combined with complete bed rest. Others advocate administration of the drug for from 4 to 12 months with the addition of para-amino salicylic acid to delay development of streptomycin resistance. Vitamin supplements and blood transfusion and other supportive measures should be used.

healthy person and may be either caseous pneumonic or caseous bronchopneumonic in type. The onset and course of the infection resemble those of the pneumonias. *Acute lobar pneumonic tuberculosis* is an exudative process with symptoms resembling lobar *pneumonia at onset. The rusty sputum and* leucocytosis of the pneumonia, *however,* are usually *absent and there is a greater remission of temperature than in pneumonia, and there may be a slight hemoptysis.* The

disease is progressive in character, with rapid loss of weight prostration, and early death Caseation and necrosis occur rapidly but tubercle bacilli rarely appear until after the tenth day If fibrosis should occur, the patient may recover *Acute bronchopneumonic tuberculosis* is a lobular form of acute tuberculosis occurring chiefly in children and young persons with sudden onset and symptoms of an acute bronchopneumonia The lesions are widespread, involving an entire lung or portions of both lungs Extensive cavitation and caseation occur, but the lesions are usually small, due to short duration An initial dry cough becomes productive of copious purulent sputum the fever rises (with daily remissions) and the patient may become prostrate and cyanotic and die within a few days or weeks In these acute forms the inflammation is exudative in type Sometimes, in the untreated case recovery does occur after 6 or 8 weeks with resorption of the exudative elements and replacement by a fibrotic or productive process The case then becomes chronic

*Chronic productive tuberculosis* is of two forms, chronic ulcerative tuberculosis and chronic fibrotic tuberculosis Extension of the inflammatory process may be followed by periods of apparent stability The chronic forms of the disease are proliferative in character rather than exudative as in acute pulmonary tuberculosis, with a gradual development of fibrous tissue Destruction and repair may be taking place simultaneously in the affected lung Usually the infective process occurs at or near the apex of the lung it may extend to other parts of the lung to form a chronic ulcerative tuberculosis with cavity formation or undergo healing with formation of fibrous tissue, leading to chronic fibroid tuberculosis *Chronic ulcerative tuberculosis* or fibro ulcerative tuberculosis is characterized by repeated formation of areas of ulceration necrosis, and cavitation as periodic break downs in resistance occur This form of the disease is the most common and usually occurs in persons between the ages of 30 and 60 The onset may be insidious or may be sudden with severe symptoms which later subside leaving the patient incapacitated Signs of an exudative localized lesion with consolidation may be observed Cavitation and caseation are indicated by profuse purulent, and bacilli laden expectoration, hectic fever, night sweats, and hemoptysis In some cases, the inflammatory reaction is localized in the area of the initial infection the tubercle walled off by a fibrous wall These nodules may be quiescent until the caseous material breaks through the wall as necrosis develops liberating tubercle bacilli which produce other nodules in ad adjoining areas With each recurrence the lesion becomes more extensive with formation of local lesions which coalesce to form larger ones If the cavities are small, the fused areas may be converted into a dense fibrotic scar If a cavity is large, it may remain partially open but the partially occluded cavity may become imbedded in dense indurated tissue which confines the disease to a compact area permitting the patient to remain apparently well for a number of years However necrosis may occur and again liberate the enclosed tubercle bacilli *Chronic fibrotic tuberculosis* may follow an exudative process Healing may follow formation of the fibrotic tissues but ulcerative and fibrotic tuberculosis may coexist in various stages of healing The fibrotic tuberculosis may exist for years before symptoms are noted Fibrosis usually occurs when the disease is of long duration and is the type generally observed in patients over 50 The duration of the process not the age of the patient is the principal factor When the fibrosis is of considerable extent, permanent shrinking may occur in the lung, with displacement of the heart and mediastinum and retraction of the chest wall There may be a compensatory emphysema in the less affected lung In these cases tubercle bacilli may be scanty or absent from the sputum for long periods of time Various degrees of bronchiectasis may be present and these are hard to distinguish from small tuberculous cavities

## CLASSIFICATION

The classification adopted by the National Tuberculosis Association, seems the most acceptable ' By primary tuberculosis is meant those morbid processes which

follow directly and uninterruptedly the first implantation of tubercle bacilli

"Reinfection tuberculosis is a new infection in a person in whom a primary infection has been healed It is not always possible to determine, even at autopsy whether the infection is a primary one or a reinfection Extension of infection from a reactivated primary lesion may be thought of as an exacerbation of the process not a reinfection

culture or animal inoculation When sputum specimens are unobtainable or inadequate or their authenticity is in doubt examination by culture or animal inoculation should be made of fasting gastric washings or aspirated pulmonary secretions The period of inactivity must have existed for at least 6 months and should be indicated according to length of time, as inactive 6 months inactive 2 years' *etc*

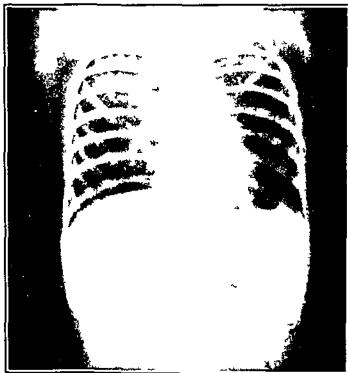

FIG 153 —Primary pulmonary tubercular infection arrested

A clinical classification is proposed in *Diagnostic Standards* to indicate (*a*) the status of the activity of the lesions according to symptomatic laboratory and roentgenologic findings (inactive arrested active or activity undetermined) and (*b*) the status of the patient in terms of exercise (not ambulatory ambulatory *etc*)

*Inactive* lesions are those in which there is *x* ray evidence of stability or extremely slow shrinkage and no *x* ray evidence of any cavitation Furthermore there are no symptoms of tuberculous activity and the sputum tests are repeatedly negative on concentration and microscopic study and on

For *arrested* lesions the symptomatic and roentgenologic requirements are the same as for inactive lesions, but the laboratory requirements are different When sputum specimens or gastric contents have proved negative on microscopic examination of concentrates but not of cultures or animal inoculations the lesions are considered arrested Arrested cases also include those in which culture or animal inoculation proves to be positive and among many concentrated specimens of sputum examined an occasional positive is found microscopically The period of arrest must have existed for at least 3 months and should be indicated

disease is progressive in character, with rapid loss of weight, prostration, and early death. Caseation and necrosis occur rapidly but tubercle bacilli rarely appear until after the tenth day. If fibrosis should occur, the patient may recover. *Acute bronchopneumonic tuberculosis* is a lobular form of acute tuberculosis occurring chiefly in children and young persons, with sudden onset and symptoms of an acute bronchopneumonia. The lesions are widespread, involving an entire lung or portions of both lungs. Extensive cavitation and caseation occur but the lesions are usually small, due to short duration. An initial dry cough becomes productive of copious purulent sputum, the fever rises (with daily remissions), and the patient may become prostrate and cyanotic and die within a few days or weeks. In these acute forms, the inflammation is exudative in type. Sometimes in the untreated case, recovery does occur after 6 or 8 weeks, with resorption of the exudative elements and replacement by a fibrotic or productive process. The case then becomes chronic.

*Chronic productive tuberculosis* is of two forms: chronic ulcerative tuberculosis and chronic fibrotic tuberculosis. Extension of the inflammatory process may be followed by periods of apparent stability. The chronic forms of the disease are proliferative in character rather than exudative as in acute pulmonary tuberculosis, with a gradual development of fibrous tissue. Destruction and repair may be taking place simultaneously in the affected lung. Usually, the infective process occurs at or near the apex of the lung; it may extend to other parts of the lung to form a chronic ulcerative tuberculosis with cavity formation or undergo healing with formation of fibrous tissue leading to chronic fibroid tuberculosis. *Chronic ulcerative tuberculosis* or fibro-ulcerative tuberculosis is characterized by repeated formation of areas of ulceration, necrosis and cavitation as periodic breakdowns in resistance occur. This form of the disease is the most common and usually occurs in persons between the ages of 30 and 60. The onset may be insidious or may be sudden, with severe symptoms which later subside leaving the patient incapacitated. Signs of an exudative localized lesion with consolidation may be observed. Cavitation and caseation are indicated by profuse, purulent, and bacilli-laden expectoration, hectic fever, night sweats, and hemoptysis. In some cases the inflammatory reaction is localized in the area of the initial infection, the tubercle walled off by a fibrous wall. These nodules may be quiescent until the caseous material breaks through the wall as necrosis develops, liberating tubercle bacilli which produce other nodules in adjoining areas. With each recurrence the lesion becomes more extensive, with formation of local lesions which coalesce to form larger ones. If the cavities are small, the fused areas may be converted into a dense fibrotic scar. If a cavity is large it may remain partially open, but the partially occluded cavity may become imbedded in dense indurated tissue which confines the disease to a compact area, permitting the patient to remain apparently well for a number of years. However, necrosis may occur and again liberate the enclosed tubercle bacilli. *Chronic fibrotic tuberculosis* may follow an exudative process. Healing may follow formation of the fibrotic tissues but ulcerative and fibrotic tuberculosis may coexist in various stages of healing. The fibrotic tuberculosis may exist for years before symptoms are noted. Fibrosis usually occurs when the disease is of long duration and is the type generally observed in patients over 50. The duration of the process, not the age of the patient, is the principal factor. When the fibrosis is of considerable extent, permanent shrinking may occur in the lung with displacement of the heart and mediastinum and retraction of the chest wall. There may be a compensatory emphysema in the less affected lung. In these cases tubercle bacilli may be scanty or absent from the sputum for long periods of time. Various degrees of bronchiectasis may be present and these are hard to distinguish from small tuberculous cavities.

## CLASSIFICATION

The classification adopted by the National Tuberculosis Association seems the most acceptable. By primary tuberculosis is meant those morbid processes which

follow directly and uninterruptedly the first implantation of tubercle bacilli

Reinfection tuberculosis is a new infection in a person in whom a primary infection has been healed It is not always possible to determine even at autopsy, whether the infection is a primary one or a reinfection Extension of infection from a reactivated primary lesion may be thought of as an exacerbation of the process not a reinfection

culture or animal inoculation When sputum specimens are unobtainable or inadequate or their authenticity is in doubt examination by culture or animal inoculation should be made of *fasting gastric washings* or aspirated pulmonary secretions The period of inactivity must have existed for at least 6 months and should be indicated according to length of time as inactive 6 months inactive 2 years *etc*

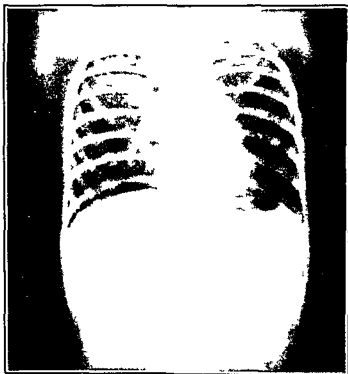

Fig 153 —Primary pulmonary tubercular infection arrested

A clinical classification is proposed in *Diagnostic Standards* to indicate (*a*) the status of the activity of the lesions according to symptomatic laboratory and roentgenologic findings (inactive arrested active or activity undetermined) and (*b*) the status of the patient in terms of exercise (not ambulatory ambulatory *etc*)

*Inactive* lesions are those in which there is *x* ray evidence of stability or extremely slow shrinkage and no *x* ray evidence of any cavitation Furthermore there are no symptoms of tuberculous activity and the sputum tests are repeatedly negative on concentration and microscopic study and on

For *arrested* lesions the symptomatic and roentgenologic requirements are the same as for inactive lesions but the laboratory requirements are different When sputum specimens or gastric contents have proved negative on microscopic examination of concentrates but not of cultures or animal inoculations the lesions are considered arrested Arrested cases also include those in which culture or animal inoculation proves to be positive and among many concentrated specimens of sputum examined an occasional positive is found microscopically The period of arrest must have existed for at least 3 months and should be indicated

according to length of time as "arrested 6 months," "arrested 2 years," *etc* *

*Active* lesions are those usually showing radiographic evidence of progression or retrogression although, occasionally, some are stationary. Clinical evidence of tuberculous origin may be present or absent. Almost always the sputum and gastric contents contain tubercle bacilli but occasionally repeated cultures and animal inoculations may fail to reveal bacilli. Very rarely the tuberculin test is negative. The period of activity if known should be indicated as "active 5 months," "active 2 years," *etc*

*Activity undetermined* applies to lesions whose activity cannot be determined even after adequate laboratory and roentgenologic studies. The provisional status may be indicated by "probably active" or "probably inactive."

The exercise status of the patient should be designated as follows: (I) Patient is not ambulatory; (II) patient has been ambulatory for less than one hour daily; (III) patient has been ambulatory for one hour daily for a period of 2 months; (IV) patient has been ambulatory for at least two hours daily for a period of at least 2 months; (V) patient is living under ordinary conditions of life. A patient therefore may be designated "inactive (6 months) III," *etc*

FIG 154 —Pulmonary tuberculosis minimal

A further classification is well defined in *Diagnostic Standards* to indicate the extent of pulmonary lesions. Thus the patient may have pulmonary tuberculosis that is minimal, moderately advanced or far advanced.

*Minimal* lesions are slight infections (without demonstrable excavation) confined to a small part of one or both lungs. Regardless of distribution the total extent of lesions shall not exceed the equivalent of the volume of lung tissue which lies above the second chondro-sternal junction and the spine of the fourth or body of the fifth thoracic vertebra on one side.

* There is not entire agreement on use of the classification "arrested." Salkin prefers use of a term which indicates an approach to inactivity such as "improved" or "quiescent." (Am Rev Tuberc 1951 *63* 721) Steele prefers to call this group "apparently inactive" and limited to patients whose pulmonary secretions are negative on concentration and have not been cultured because of lack of facilities. The Wisconsin State Board of Health omits the term "arrested" and calls all lesions active or inactive. (*Ibid* p 117)

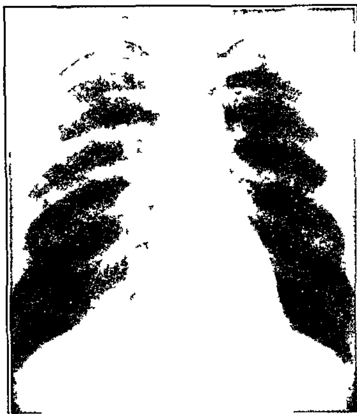

Fig 155 —Moderately advanced pulmonary tuberculosis

Fig 156 —Far advanced pulmonary tuberculosis

*Moderately advanced* lesions may involve one or both lungs but shall not exceed the following limits (1) slight disseminated lesions which may extend through not more than the volume of one lung or the equivalent in both lungs, (2) dense and confluent lesions which may extend through not more than the equivalent of one third of the volume of one lung, (3) total diameter of cavities less than 4 cm '

*Far advanced* lesions are those more extensive than moderately advanced A further suggestion is made that the location of lesions be designated by bronchopulmonary segments and the segments classified according to the recommendations of the American Association for Thoracic Surgery

## CLINICAL MANIFESTATIONS

The symptoms and signs of tuberculous disease are not pathognomonic since they are similar to those of many other types of pulmonary infection In many instances the initial infection begins with a small area of exudative bronchopneumonia which enlarges very slowly over a period of months the patient may remain symptomless for a considerable time When symptoms finally occur and the patient is first brought under observation the disease may be far advanced beyond the stage when treatment is most effective Even in advanced cases the symptoms may be mild This emphasizes the need for early case finding and the values of mass *x* ray studies

The onset may be relatively sudden following what seems to be a bad cold or an attack of influenza which becomes progressively worse This may occur soon after the primary infection or develop many years after the disease has existed and the original focus has become calcified

*Fever* is one of the commonest manifestations of tuberculosis *it may be constant or* intermittent In minimal cases, a slight elevation of temperature may be observed in the late afternoon sometimes it is a rise of only half a degree in 24 hours As the disease progresses, the temperature may attain high levels, remaining unchanged for a number of weeks or months, then suddenly subside, only to reappear in a grippe like episode Even with a temperature of 102° or 103° F , the patient may remain comfortable except for a feeling of warmth and flushing of the face The fever may be accompanied by drenching sweats particularly at night

*Cough* is one of the most constant signs at first being non productive It is noted in over 50 per cent of the patients and at first may occur only in the morning in an effort to discharge accumulations of fluid in the bronchi but it becomes increasingly distressing with difficulty in raising these exudates Occasionally the cough is of neurotic origin and can be controlled

*Expectoration* a common symptom rarely occurs *in early or minimal pulmonary* tuberculosis At first the sputum may be small in amount about 1 oz daily and consist of only clear mucus Later with the

development of cavitation, 2 or 3 oz of a caseous colorless material which with progress of the disease becomes copious and yellowish green may be discharged daily A sudden increase in the amount of sputum may indicate that a recently formed lesion has penetrated a bronchus or that a bronchopleural fistula has formed On the other hand sudden decrease in the amount of sputum may indicate bronchial obstruction The sputum becomes foul only when a secondary infection by anaerobes has taken place

*Hemoptysis* may occur as only a faint streaking of blood in the sputum, or as a hemorrhage of a dram or more of blood It may be one of the earliest symptoms or may never occur at all The bleeding usually arises from ulceration of a blood vessel in a cavity or acute congestion around the lesion Usually the hemorrhage does not exceed 300 cc of blood and is followed by clotting which seals the opening Clots may be coughed up for several days or may be retained thus causing blocking of a bronchus and collapse of a lobe The hemorrhage may occur suddenly often during sleep at night and occasionally may be so massive as to cause drowning of the patient

*Hoarseness*, intermittent or persisting may indicate tuberculous lesions of the larynx or may merely be the result of incessant coughing *Wheezing* follows bronchial obstruction caused by mucous collections

*Dyspnea* on exertion in the early stage may accompany weakness or toxemia It may be continuous in advanced cases because of fibrotic changes in the lungs or may indicate serious myocardial weakness It may occur suddenly following spontaneous pneumothorax or may result from a rapidly accumulating pleural effusion

*Pain in the chest* aggravated by respiratory effort is a common symptom and an evidence of pleuritic involvement It may occur in any stage of the disease

Other symptoms occasionally observed include headache when the temperature is elevated increased pulse rate in the presence of toxemia and either increased or decreased digestive activity, according to the amount of toxemia present Constipation may be caused by the inactive life of the patient

These varied symptoms rarely if ever, all occur in one individual Some patients manifest few symptoms even in far advanced disease Furthermore most of these symptoms are observed in various combinations in other diseases of the lung and for this reason cannot be regarded as highly significant Only when considered together with the history of the patient and the laboratory and radiologic evidence are they important in making the diagnosis

Physical signs are also frequently minimal and not specifically characteristic However they should be observed to give a clear picture of the condition These signs may be absent in advanced cases with cavitation but, on the other hand they may be manifested in healed cases in which there are complications such as emphysema or bronchiectasis Palpation will reveal any displacement of the trachea or heart due to retraction of the lung caused by fibrosis or atelectasis Impairment of the percussion note at the apex of the lung is an early and reliable physical sign It may be noted long before development of gross consolidation of the lung and is generally more marked in the supraspinous fossa than below the clavicle Dullness on both sides may be noted if there is infiltration of the upper portions of the lungs this will increase in extent as consolidation progresses If a large cavity is present and not entirely filled with secretion, percussion over its site may produce resonance and tympany

*Auscultatory findings* will be dependent upon the location of the infection its closeness to the periphery of the lung and the amount of consolidation and cavitation Breath sounds may vary from bronchovesicular to bronchial breathing depending upon the extent of normal tissues between the affected regions Rales if present may be either fine or coarse depending upon the size of the bronchial ramifications and the secretion therein On slight cough at the end of a forced expiration followed by slow deep inspiration rales may be noted both during coughing and at the end of inspiration

Clubbing of the fingers except in old fibrotic cases will not be noted unless there is concurrent heart disease empyema, or bronchiectasis

## DIAGNOSIS

The *history* of the patient is of great importance in making a diagnosis of pulmonary tuberculosis Information regarding past respiratory illnesses, particularly a history of pleurisy with effusion, known tuberculosis in the family or other contacts, or employment in certain types of industry is of value in arriving at a diagnosis In the majority of cases, the contact is not known The final diagnosis is based upon the history, the symptoms physical examination, and the results of special studies especially sputum examination and $x$ ray of the chest

*Sputum examination* demonstrating the presence of tubercle bacilli is conclusive evidence of the disease A negative finding however cannot without other confirmation be considered proof of the absence of tuberculosis Sputum examinations must be conducted with great care The sputum must be collected over a 24 hour period its volume measured its consistency noted and tubercle bacilli searched for in smears stained (preferably) by the Ziehl Neelsen technique Concentrated sputum specimens should be examined when the bacilli are not demonstrated When there is little expectoration the specimen may be collected over a 24- to 72 hour period Two processes in preparation of the concentrated sputum are used (1) homogenization or emulsion and (2) concentration by gravity centrifugalization or separation When direct-smear and concentrated sputum studies are negative for tubercle bacilli but clinical evidence points to a tuberculous infection culture on desirable media or guinea pig inoculation are indicated If no sputum can be obtained the fasting gastric contents should be examined for bacilli

Sputum or gastric contents should never be considered negative for tubercle bacilli until at least three satisfactory specimens taken at least one week apart are negative by culture or by animal inoculation Finding one sputum specimen negative does not give assurance that another specimen will not reveal the presence of tubercle bacilli

*Gastric contents* collected on awakening may prove of value in demonstrating the presence of bacilli in children who swallow their sputum or in patients from whom sputum cannot be obtained This has proved an effective method of obtaining bacterial evidence but smears of gastric washings are unreliable because of the presence of other acid fast bacteria The washings therefore, must be cultured or inoculated into guinea pigs A series of negative examinations of sputum and/or gastric washings in the presence of cavitation may be considered evidence of the nonexistence of a tuberculous process

*Laryngeal swabs* on culture may be helpful but cannot be relied upon if no acid fast organisms are found

*Bronchial lavage* whereby 20 cc of warm saline solution are introduced into the bronchial tree and the expectorant then examined for acid fast organisms is favored by some clinicians There may be hazard of bronchial dissemination in this procedure

*Blood Changes* —During acute exacerbations, the polymorphonuclear leukocyte count may rise as high as 10 000 to 18 000 the neutrophils rising up to 80 per cent In early acute active tuberculous pneumonia and in acute miliary tuberculosis the white cell count may be elevated to more than 20 000 and the polymorphonuclear count to over 95 per cent In chronic cases, the white cell count tends to remain normal The neutrophils increase with the progress of the disease decrease in their number usually accompanies general improvement However the lymphocyte monocyte *ratio* is of limited value since this may be altered by intercurrent infections

The erythrocyte count and the hemoglobin content generally remain normal in chronic cases but may decrease in active and acute cases until a mild anemia is observed This anemia does not become marked even in far advanced cases unless extrapulmonary complications are present

The sedimentation rate may remain normal in minimal tuberculous disease but is usually elevated in the advanced febrile stages A normal sedimentation rate does

not signify inactivity or favorable progress of the disease since it may be found normal both in early active cases and in chronic cases

*Urine examination* may reveal the presence of tubercle bacilli in patients with renal tuberculosis There may be no other urinary abnormalities Finding these bacilli in the urine should initiate search for pulmonary tuberculosis if it is not already known to be present On the other hand pus cells a persistently marked increase in the number of erythrocytes or persistent albuminuria in the urine of a patient with pulmonary tuberculosis should lead to a search for the renal tuberculosis

The *tuberculin test* is a valuable means of revealing tuberculous infection A positive reaction always indicates the presence of such a process, but gives no information regarding the activity of the disease, the test indicating only that at some period in his life the patient has been infected with tubercle bacilli When no reaction is elicited after repeated doses of tuberculin it is generally assumed that no infection is present However the dosage may have been too small to indicate infection in well-healed lesions or an acute infectious disease may also have been present such as measles or influenza Whenever there is a suspicion of a tuberculous process the test should be used In persons with long-standing lesions only large doses may produce a reaction

The intracutaneous Mantoux test or the Vollmer patch test may be used For routine case finding the Mantoux method is generally preferred Either 0 1 mg of old Tuberculin (OT) or purified protein derivative (PPD) with first or second strength test dose is injected into the superficial layer of skin In very ill patients the initial concentration should be only 0 01 mg of OT or 0 00001 mg of PPD A reddened wheal with induration and edema of the subcutaneous tissues may be observed 72 to 96 hours after the test in positive cases Any redness due to trauma will have faded by that time The degree of redness is not significant but the reaction may be intense in recent infections or reinfections If negative results are obtained the test should be repeated after 4 or 5 days with a higher concentration of the testing material No reaction will be noted in the pre allergic stage (3 to 7 weeks after the primary infection), nor during the terminal stage, when the pulmonary tissues are desensitized (anergic phase)

The Vollmer patch method consists of application to the skin for a 48 hour period of a piece of gauze impregnated with dried tuberculin After 72 to 96 hours a red papular, sometimes vesicular eruption may be noted in positive cases This method is often preferred in children

The significance of a positive tuberculin test varies with the age of the individual A positive test in children under 2 years of age may indicate the presence of an active lesion unless radiologic findings examination of the gastric contents and careful observation prove otherwise Active disease is not necessarily indicated by a positive test in young children although the younger the child the more likely the lesion is to be active especially if there is a history of recent contact A reactor should be retested every 3 to 5 years to determine whether the infection has disappeared

Certain limitations in tuberculin skin testing should be noted First a negative test should be repeated within 6 weeks if the contact has been recent since hypersensitivity may not yet have been developed Second not infrequently a negative finding is obtained in cases of far advanced generalized or meningeal tuberculosis in moribund patients and in the presence of acute infectious diseases such as measles and scarlet fever Third allergic manifestations may cease in patients with calcified foci representing completely healed earlier lesions Finally it has been demonstrated that a small percentage of clinically tuberculous patients although in a very advanced stage of the disease may yield a negative reaction for this reason when clinical evidence strongly favors a diagnosis of tuberculosis a negative test may not be clinically significant

*Bone marrow examinations* may reveal the presence of bacilli in cases of hematogenous tuberculosis The process whereby these bacilli reach the bone marrow has

not been determined—whether tubercle bacilli extending from a caseous focus through the lymphatics reach the thoracic duct and then enter the circulation, whether direct extension of a caseous lymph node into a vein forms a tubercle within the vein for hematogenous seeding, whether caseous foci are a disseminating source or whether tubercle bacilli drain from an active extrapulmonary focus to the regional caseous lymphnode and then, by way of the lymphohematogenous route, finally reach the circulation is not known No one mechanism may be responsible and any one or a combination of two or more of these processes may cause invasion of the blood stream When hematogenous dissemination is present without pulmonary lesions, then *x* ray study and bacteriologic examination of the sputum and gastric washings are valueless However, in many cases, the lung ultimately becomes involved Katz noted that in three-quarters of his hematogenous cases, bone marrow studies were positive on the first examination but the test cannot be considered negative until three aspirations have been made The bone marrow may contain tubercle bacilli even before they can be identified in the sputum, the gastric washings, the lymph nodes or the spinal fluid Since it has been demonstrated that early administration of streptomycin may inhibit or arrest a tuberculous process and since a bone marrow examination may reveal the presence of the disease before localization has occurred bone marrow examination may also indicate the effectiveness of streptomycin therapy After the disease becomes quiescent the bone marrow may still remain positive an indication *that the bacilli have remained resistant to* streptomycin and that further use of the drug may be without value

*X ray examinations* are indicated in all suspicious cases of pulmonary infection When a large group of apparently healthy individuals are studied roentgenologically most of those found to have pulmonary tuberculosis have minimal lesions Of those who report to physicians because of pulmonary symptoms a majority will show evidence of moderately or far advanced tuberculous processes Some having negative roentgenograms one year later may show shadows indicating moderately or well advanced tuberculous lesions Chronic tuberculosis may have existed for a considerable period yet show no evidence of advancement, so that it cannot be determined when the infection first occurred

Except for tubercle bacilli tests, roentgen examination furnishes the most conclusive evidence of the disease It also indicates how effective therapeutic measures are whether there has been healing of reinfective parenchymal tuberculosis and whether any cavitation, fibrosis or calcification is present

Fluoroscopic study of the lungs though inadequate for detecting early tuberculous lesions, is helpful in defining the position, the contour, and the movement of the cardiac and diaphragmatic shadows and in showing the mediastinal areas These cannot be determined by routine *x* rays of the chest Photo fluorograms of these images can be made on small films and enlarged for study However since fluoroscopy fails to reveal from 10 to 15 per cent of the minimal lesions it cannot be substituted for radiography

Certain limitations in roentgenologic diagnosis have been noted First the usual *x* ray film will show only 75 per cent of the lung because of shadows of the heart and diaphragm Second though numerous lesions may exist within the field *x* rayed they may not cast perceptible shadows either because they are too small to do so or because they are not of the necessary consistency to absorb *x* rays Third an accurate diagnosis of the pulmonary lesions cannot be made from their shadows alone since many of these shadows are observed *in other pulmonary* diseases Fourth neither progression nor retrogression of the tuberculous process can be determined unless new films are taken periodically Finally the location of pulmonary lesions casting shadows cannot be regarded as a satisfactory diagnostic criterion Though chronic tuberculosis usually occurs in the upper part of the lung it often develops first in the lower part Furthermore though nontuberculous conditions usually appear in the lower part of the lung they sometimes occur in the upper part

*Differential Diagnosis*.—Most of the radiologic findings in pulmonary tuberculosis are also observed in such nontuberculous conditions as diseases of the lymph glands and blood vessels, bronchial disorders, inflammatory parenchymal lesions, neoplasms, pleural lesions, and many other pulmonary affections, including those secondary to cardiovascular disturbances.

*Upper respiratory infections*, such as sinusitis, tonsilitis, bronchitis, influenza and protracted colds, may simulate pulmonary tuberculosis, particularly with respect to the stubborn or recurrent cough. Frequently, adequate treatment of the paranasal sinuses and removal of infected tonsils will cause the symptoms to disappear. Examination of the sputum will fail to show tubercle bacilli.

*Chronic bronchitis* frequently suggests tuberculosis. The cough may be strenuous and dry, or productive of small quantities of viscid mucoid sputum or large quantities of mucopurulent and occasionally blood-tinged sputum, depending upon the underlying cause. No persistent cough, however, should be considered indicative of chronic bronchitis unless tuberculosis has been carefully ruled out. X-ray examination in cases of bronchitis may reveal thickened hilum shadows, markedly increased bronchovascular linear markings, particularly toward the bases, and evidence of emphysema.

*Bronchiectasis* commonly reveals symptoms resembling those of tuberculosis. Chills, fever and sweating, however, occur more persistently in tuberculosis. Bronchiectasis may be suspected when the lesion is situated in the lower lobe, although it occasionally also occurs in the upper lobe. The roentgenogram may be normal or show increased linear densities extending downward from the hilar areas. If bronchiectasis is suspected, failure to find acid-fast organisms should rule out tuberculosis. But the two diseases may exist concurrently. *Pulmonary hemorrhage* which may occur with either disease sometimes leads to an erroneous diagnosis.

The *pneumonias*, except for a frank lobar pneumonia, may be confused with tuberculosis, and a tuberculous pneumonia is easily confused with an acute pneumonia; only when it fails to respond to drug therapy is the error recognized.

Primary atypical pneumonia may present clinical and radiologic pictures similar to those of tuberculosis, but in the former the absence of cavitation, the absence of tubercle bacilli in the sputum, and eventual and complete resolution of the pulmonary lesion will establish the diagnosis.

Friedländer's pneumonia is chiefly distinguished from tuberculosis by the rapid spread of consolidation from one lobe to another and the copious expectoration of blood-tinged sputum of a mucinous, chocolate-pudding nature. Examination of the sputum will usually establish the diagnosis.

Bronchopneumonia is distinguished from early tuberculosis by its acute onset and rapid abatement of symptoms.

Lipoid pneumonia is differentiated from tuberculosis by demonstration of oil droplets in the sputum. Usually a history of the use of oily medications can be obtained from patients with lipoid pneumonia.

The response to penicillin therapy distinguishes all types of pneumonia from tuberculosis, since the drug has no effect upon the latter disease.

*Loeffler's syndrome*, except for the variability of the roentgenologic findings which may be transitory and migratory, may be mistaken for tuberculosis. Fatigue, malaise, cough sometimes associated with chest pain and productive of a small amount of sputum, mild asthmatic attacks, bronchitis, and some elevation of temperature should suggest the former disease. The blood picture shows a fairly high leukocytosis, somewhat elevated sedimentation rate and a high eosinophile count. Diagnosis depends upon serial roentgenologic observations and blood and sputum studies.

*Abscess of the lung* is often difficult to distinguish from a tuberculous lesion radiologically; however, the abscess usually shows more precise outlines than the tuberculous lesion. The abscess may be obscured by exudation, atelectasis and pneumonitis; when visible it is a fairly dense homogenous round circumscribed or irregularly shaped shadow. When necrosis and empyema de-

velop, the lesion is again overshadowed Bronchoscopic examination will aid in the differential diagnosis Penicillin may be effective if the lesion is an abscess, if the lesion is tuberculous penicillin will not be effective Intensive search for tubercle bacilli should be made in all cases of suspected lung abscess

*Bronchiogenic carcinoma* with cough hemoptysis dyspnea fever chest pain, unilateral wheezing and weight loss is suggestive of tuberculosis especially in the middle aged The radiologic findings are often similar to those of tuberculosis

Bronchoscopy may permit direct view of the growth unless it is in the hilar area but in some cases will not reveal the growth until it bulges or breaks into a large bronchus The tumor may be indicated by a narrowed and distorted bronchial tree with congestion edema and obstruction Cytologic study of bronchial aspirations or a punch biopsy may reveal cancer cells but the latter is not generally recommended A biopsy of a superficial metastatic lesion in a lymph node may also be diagnostic Diagnostic thoracotomy and bronchography are other aids to diagnosis

*Hodgkin s Disease* — A study of the lymph nodes and skin lesions helps reveal the presence of Hodgkin s disease Tuberculosis which may exist concurrently is discovered by sputum examination

*Cardiovascular disturbances* may also suggest tuberculosis Hemoptysis frequently occurs in both mitral stenosis and hypertension Chronic pulmonary congestion may lead to pulmonary fibrosis and infected pulmonary infarcts may develop into abscesses simulating tuberculous cavitation Positive diagnosis rests upon the laboratory findings

*Pulmonary fibrosis and emphysema* may occur with or without chronic disseminated tuberculosis Chronic cough hemoptysis and increasing weakness may give rise to a suspicion of tuberculosis

*Sarcoidosis*, radiologically shows enlarged lymph nodes usually bilateral and symmetrical involving the peribronchial rather than the peritracheal nodes The extensive x ray changes are entirely out of proportion to the symptoms, for the patients often appear to be in excellent health If the cervical nodes are enlarged, biopsy may be required to distinguish sarcoidosis from tuberculosis

*Pneumoconioses*, of which silicosis siderosis, anthracosis and asbestosis are the most common types, are occupational diseases with few physical signs except in the presence of complications, but they give rise to conditions mimicking tuberculosis The marked dyspnea is in contrast to the general good condition However, there is little weight loss there is usually no fever and the fatigue is much less pronounced than in tuberculosis The radiologic appearance is similar to that of tuberculosis

Some of the pneumoconioses particularly silicosis seem to favor the development of tuberculosis When marked exudatione consolidation and cavitation are present, an associated tuberculosis should be suspected and tubercle bacilli searched for in the sputum

*Coccidioidomycosis* and other mycotic diseases causing densities cavitation and miliary spread may so closely resemble tuberculosis that only immunologic or bacterial study will distinguish them from tuberculosis

*Psittacosis* (ornithosis) may in mild cases be confused with pulmonary tuberculosis The disease can be diagnosed only by recovery of the causative virus from the sputum

## Complications

Pulmonary tuberculosis is not uncommonly complicated by tuberculous processes in other parts of the body Only rarely however does primary tuberculosis occur outside the lung when it does involvement of the lung is almost certain to follow Involvement of other organs may follow dissemination of the tubercle bacilli by way of the blood or the lymph or it may occur through spread of the infection to areas adjoining the lung

*Pleural involvement* is one of the most frequent complications of pulmonary tuberculosis especially in acute cases Pleural effusion in children is always serious and should arouse a suspicion of tuberculosis A patient may complain of pain in the chest

but fluoroscopic and roentgenologic examination may fail to reveal any evidence of pleural effusion until some time after the pain has subsided. Except in mild dry pleurisy, pain in tuberculous pleurisy is followed by slight fever, which increases as the pleural fluid develops, at which time the pain diminishes. The symptoms are those of any other pleural effusion. A positive diagnosis of tuberculous pleurisy is made only by laboratory studies of the fluid or by thoracoscopic examination. Some clinicians believe that thoracentesis is indicated only when examination of the fluid is desired and the effusion is so great as to make x-ray study impossible. Pneumothorax is not advised in simple tuberculous pleurisy, since it may lead to tuberculous empyema.

When the exudate of a tuberculous pleural infection becomes purulent, tuberculous empyema develops. Tuberculous empyema may develop spontaneously or as a complication of artificial pneumothorax. The fluid is thick and purulent and usually contains tubercle bacilli. If no fistula is present, Hayes advises repeated aspirations, pleural lavage with such disinfecting and detergent agents as azochloramide and tergitol, and maintenance of a negative intrapleural pressure. Aspirations and irrigations are usually ineffective in preventing further thickening of the fluid, and the empyema becomes chronic unless the lung can be reexpanded and the empyema quickly cleared up. If reexpansion does not occur, streptokinase may be tried; if not successful, decortication or thoracoplasty may be necessary. If a bronchopleural fistula develops, immediate intercostal drainage is required to prevent spread of infection to the opposite side. Streptomycin therapy, unsuccessful in closed treatment of tuberculous empyema, has proved valuable in local open treatment of the condition in conjunction with thoracoplasty or muscle implantation.

*Tuberculosis of the larynx* is a serious complication of pulmonary tuberculosis and usually indicates progressive disease.

Early cases may be asymptomatic. A hacking cough may develop because of tickling or scratching sensations or excessive dryness in the throat. Voice changes occur with vocal cord involvement, hence chronic hoarseness should suggest tuberculosis. Pain occurs only in advanced cases and increases with coughing. Ulcers may form on the vocal cords and give them a moth-eaten appearance, or the cords may become edematous. Severe laryngeal pain may be referred to the ear. Dyspnea caused by laryngeal obstruction rarely occurs. Dysphagia and odynophagia, when present, interfere with nutrition.

*Tuberculous tracheobronchitis* may result from direct extension of the infection or dissemination of the bacilli by the blood or the lymph. It is said to occur in approximately ten per cent of the cases of pulmonary tuberculosis and is a serious complication. If limited to the smaller bronchi in the vicinity of a caseating focus, it occasionally brings about collapse of the lung; on the other hand, it may distend a small cavity arising from the liquefied focus. The larger bronchi, even at some distance from the original focus, may become involved; if an incomplete obstruction results, emphysema will develop; if the obstruction is complete, atelectasis will follow.

Ulcerative tuberculous tracheobronchitis may cause the appearance of tubercle bacilli in the sputum in cases without x-ray evidence of pulmonary tuberculosis. The nonulcerative nonstenotic type is the most common. Wheezing, paroxysmal coughing and unexplained dyspnea are common symptoms. Gross obstruction of the bronchus rarely occurs but, when it does, gives a poor prognosis. In such a case persistent cough and difficult expectoration are noted, together with rhonchi at the site of obstruction that are loud enough to be heard without a stethoscope.

Treatment should attempt to reestablish and maintain bronchial drainage. For simple or tracheal ulcers, cauterization with 30 per cent silver nitrate solution or electrocauterization is recommended. Secretions should be aspirated repeatedly. Streptomycin therapy is advised in acute or subacute cases. Inhalation therapy and the use of atropine, adrenalin, ephedrine and vaccines have also been suggested.

The prognosis is dependent upon the degree of infection when the disease is

diagnosed. Small lesions with hyperemia may heal spontaneously. In patients with a severe degree of stenosis, Cohen finds that a mortality rate of from 25 to 35 per cent may be expected some 5 years after discovery of the tuberculous tracheobronchitis. Patients with a chronic condition, however, may survive for an indefinite period under proper care.

*Tuberculosis of the digestive tract* is now being seen with decreasing frequency. Hayes reports that the stomach was found to be involved in less than 1 per cent of several thousand autopsy cases of pulmonary tuberculosis. He suggests that some of the so-called tuberculous ulcers of the stomach may be peptic ulcers secondarily infected with tubercle bacilli. However, miliary tuberculosis is a known cause of tuberculous ulceration of the stomach. The treatment is usually medical, although the ulcer may be excised if the patient's condition permits.

Tuberculosis of the intestines occurs only after cavitation has taken place in a lung and usually results, it is believed, from the swallowing of sputum containing tubercle bacilli. Rubin found intestinal tuberculosis in 65 per cent of 526 patients dying of pulmonary tuberculosis. He noted that patients under 30 develop intestinal tuberculosis twice as often as those over 50 and that it occurs more often in females than in males, except between the ages of 21 and 30. Furthermore, intestinal tuberculosis occurs twice as often in patients with laryngeal tuberculosis as in those without laryngeal infection. Fluoroscopic and gastrointestinal studies are suggested for suspected cases. The most usual site of the infection is in the ileo-cecal region, the ileum being involved in 89 per cent of patients and the cecum in 75 per cent.

In intestinal tuberculosis, there may be no symptoms or such symptoms as colic, indigestion and diarrhea alternating with constipation. The severity of the symptoms does not depend on the amount of disease; small lesions may produce many symptoms while in some patients extensive disease causes few symptoms. Loss of weight or unexplained fever may be the only symptoms. Roentgen examination may reveal the Stierlin phenomenon, that is, nonfilling of the cecum and terminal ileum with barium and irritability of the rest of the ileum and colon. Mild pain may be aggravated by eating, and there may be slight fever in the evening and subnormal temperature in the morning. The lesion may heal with improvement of the pulmonary infection. Symptomatic therapy includes strict bed rest, use of a high caloric, low protein, smooth diet supplemented with cod liver oil, tomato juice, and vitamins. Hayes and Adams recommend oxyperitoneum in suspected cases of secondary intestinal involvement either as a therapeutic test or as a means of treatment. Usually oxygen from 300 to 500 cc is injected, this being given every 5 to 7 days until the acute symptoms subside. The effects may be observed immediately or in from 24 to 48 hours. Excellent results have been achieved with streptomycin therapy. The prognosis in patients with intestinal tuberculosis is good when diagnosed early and promptly and adequately treated. Recovery depends upon cure of the lung involvement.

Ischiorectal abscesses and fistula in ano are frequently observed in patients with perianal tuberculosis. These conditions may precede the appearance of clinical symptoms. The fistulous tract should be resected, care being taken to locate the internal opening. Healing may require months.

Tuberculous peritonitis may accompany tuberculosis of the fallopian tubes, tuberculous enteritis, tuberculosis of the mesenteric nodes, or miliary tuberculosis. It is usually insidious in onset and presents mild, vague symptoms. The disease has been successfully treated with injection of 300 to 500 cc of oxygen into the peritoneal cavity, repeated at weekly intervals if necessary. Five or six treatments may suffice in acute cases, but chronic cases may require continuance for a year. If effusion is present the fluid should be aspirated before injection. To date, results of therapy with streptomycin have been excellent.

*Tuberculosis of the genitourinary organs* has greatly decreased in the past two decades. (*See* page 1033.)

Genital tuberculosis is not frequently reported; it is primarily a disease of youth

If material can be expressed from the prostate gland tubercle bacilli may be found Tuberculous lesions of the testes are rarely observed except as an extension from the epididymis Infection of the epididymides is bilateral in half the cases and may cause swelling tenderness and contour changes with extension into the vas deferens The infection may be subacute and quiescent with only slight tenderness and swelling later however it may be activated by trauma and produce acute symptoms Involvement of the seminal vessels produces discomfort at the neck of the bladder and low back pain Treatment of the pulmonary and renal tuberculosis may arrest the glandular infection

Genital tuberculosis occurs half as frequently in females as in males and in the former it most often involves the fallopian tubes with secondary spread to the uterine endometrium and ovaries Radiation therapy has been found helpful except in case of marked fever toxemia or massive lesions Sanatorium care or enforced rest is necessary the period of time required varying with the patient Use of streptomycin therapy seems promising but it is in the experimental stage

*Pregnancy in tuberculous women* when adequate care is provided need have no unfavorable effect on the tuberculosis nor need tuberculosis adversely affect the pregnancy The pregnant patient may be unaware of her tuberculous condition although it may be well advanced The practice of prenatal care has led to more frequent discovery of the condition Determination of the activity of the lesion must be made at once and the woman placed under the care of a physician experienced in treatment of tuberculosis Close relationship between the chest specialist and the obstetrician has resulted in the present good results obtained in these patients Sanatorium care for the pregnant patient with active tuberculosis should be urged The patient with a stabilized lesion should be hospitalized for some time before the expected date of delivery

The treatment of the tuberculous pregnant woman is the same as for other tuberculous patients—bed rest antimicrobial agents collapse measures and surgical therapy if indicated

A normal child can be expected whether the mother s tuberculosis is inactive or active Chances of intrauterine infection of the child are slight Since the strain of childbirth and the wide excursions of the diaphragm during labor will nullify some of the benefits obtained from the long bed rest the second stage of labor should be made as short and easy as possible Rules regarding the choice of anesthetics are the same as for any other surgical procedures in tuberculosis Caesarian section is not indicated except for the usual obstetrical reasons

The newborn infant must be removed immediately from contact with the infected mother The only real danger to the tuberculous mother occurs not during the pregnancy but after delivery If the mother attempts to care for her baby, and in addition to perform household duties she is in danger of activating her disease if it has been inactive or of making it rapidly progressive if it is active

*Tuberculosis of the bones* may occur at any age but is found most often in children Except for the primary infection there may be no evidence of tuberculosis in the lung parenchyma however search should be made for tuberculous lesions in the kidney and genital areas Tuberculosis of the spine or hip may progress rapidly Usually the tubercle bacilli slowly invade a joint from a focus near the epiphysis and extend toward the peritoneum forming bony sequestra and abscesses and causing necrosis of the bony structures Hard coughing may cause fracture of a rib usually on the anterolateral aspect of the chest Radiologic evidence is presented only after atrophy destruction and condensation take place Finding of bacilli by biopsy or bacteriologic examination confirms the diagnosis Treatment consists of complete rest nutritious diet freedom from weight bearing and later fusion of the bones and resection of joints as indicated Adjuvant therapy includes heliotherapy ultraviolet radiation and administration of streptomycin with PAS

*Tuberculous meningitis* the pathogenesis of which has long been subject to controversy, may be the terminal stage of a hematogenous tuberculosis situated within the brain (the principal focus) the spinal cord the meninges themselves the choroid plexus, or a bone in the vicinity of the central nervous system It occurs most frequently in infants between the ages of 6 and 18 months, only seldom does it occur in children over 10 It is estimated that 60 per cent of all infants and children dying of tuberculosis have meningitis A persistent uncontrollable headache and rising temperature in children are suggestive of the disease The onset of the disease is insidious and the course is protracted occasionally with remissions Nausea and vomiting may be the only symptoms Fever occurs when the disease is well advanced It may be mistaken for encephalitis suppurative meningitis convulsive states or delirium Irritability, fretfulness and personality changes may occur in the adult

Diagnosis depends on the recovery of tubercle bacilli from spinal fluid The spinal fluid may show increased protein decreased chloride and sugar some lymphocytes and a great increase in the number of neutrophils Until the advent of streptomycin treatment was merely palliative Hayes and Adames report recovery in 50 per cent of their patients treated with parenteral and intrathecal injections of streptomycin 1 mg per kg body weight up to 50 mg dissolved in 10 cc of normal saline solution This is given once a day for several days then on alternate days and finally every third day for 90 days *Iglee* advocates giving streptomycin parenterally and intrathecally in all cases of tuberculous meningitis

*Tuberculous pyopneumothorax* due to perforation of a subpleural caseous focus is very serious and may lead to death When there is a large bronchopleural fistula, air enters the pleural cavity more quickly than it can be withdrawn this demands quick aspiration and treatment for shock An in-dwelling needle or some type of continuous suction under water is required to allow escape of the air A mixed infection often results and causes a stormy course Anoxemia may be relieved by oxygen therapy Thoracotomy and intercostal drainage are indicated and should be followed by thoracoplasty or pleuropneumonectomy as soon as the patient's condition permits The latter goal may be reached more effectively by relieving toxicity by means of appropriate antibiotic therapy and chemotherapy directed against the mixed infection

*Adenitis* occurring during reinfection tuberculosis can be successfully treated radiologically Cervical and mesenteric lymph node involvement is rare Tuberculous cervical adenopathy is generally associated with bovine strain and stems from ingestion of contaminated milk The diagnosis is established by biopsy tuberculin tests, or laboratory study of discharges from a sinus Conservative therapy with ultraviolet light or roentgen rays, should be employed before surgery, since many cases respond to such therapy alone When fluctuation, abscess formation or discharging sinus is present antimicrobial therapy may be employed in conjunction with surgery Incision and drainage of softened nodes or removal of solitary nodes may be necessary For tuberculous abscesses aspiration of the pus lavage of the cavity with a 1 per cent aqueous solution of tincture of iodine and injection of oxygen into the pocket are suggested PAS solution may also be employed in abscess cavities or sinuses

*Diabetes* in patients with pulmonary tuberculosis particularly severe or inadequately controlled diabetes is a serious complication Diabetes is usually the primary disease The incidence of tuberculosis among diabetics is substantially greater than it is among the general population These facts stress the necessity of periodic chest *x* rays for all diabetics In comparison with the nondiabetic the diabetic more often presents himself with far advanced tuberculous disease of an acute exudative or pneumonic nature with evidence of marked tissue destruction caseation and cavitation

Treatment requires control of the diabetes by diet and insulin and of the tuberculosis by collapse therapy or other indicated measures particularly antimicrobial therapy Kayne points out that tuberculous diabetics frequently have too low a diet since tuber

culosis requires liberal feeding the conflict may be managed by giving increased food and adjusting the insulin requirement

Successful treatment of several elderly patients by thoracoplasty has been reported by Rubin Collapse therapy should be induced immediately without waiting for the usual period of bed rest if the diabetes becomes uncontrollable or chest symptoms develop Improvement of either condition will benefit the other

*Bronchiectasis secondary to tuberculosis* a relatively frequent finding is often unrecognized However this bronchiectasis may be significant and overshadow the tuberculosis in importance since it may determine the development of the pulmonary lesion and the direction of management The course and prognosis of pulmonary tuberculosis may be adversely influenced by secondary bronchiectasis since (1) bronchiectatic suppuration may break down an encapsulated focus or interfere with repair (2) tuberculosis in the presence of bronchiectasis may be spread by purulent secretions and hemoptyses and (3) pulmonary symptoms due to bronchiectasis may persist despite negative sputum and apparently adequate treatment for pulmonary tuberculosis Moreover collapse treatment directed toward tuberculosis may be unsuccessful as a result of secondary bronchiectasis Therefore treatment of the bronchiectasis by pulmonary resection may assume primary importance

Bronchiectasis in the tuberculous patient should be suspected when productive cough low grade fever and occasional hemoptyses persist despite sputum conversion and apparent arrest of tuberculosis and when negative sputum persists in apparent clinical or radiologic cavitary tuberculosis It must be pointed out that bronchiectasis in the sputum negative tuberculous patient may resemble active tuberculosis

The pathogenic mechanisms of bronchiectasis secondary to tuberculosis are dependent upon a combination of bronchial and parenchymal factors Of many factors bronchial obstruction and reduction in volume of aerated lung (atelectasis) appear to be the most important Bronchial infection pneumonic consolidation and pulmonary fibrosis are secondary factors

## TUBERCULOSIS IN OLDER PATIENTS

Many tuberculous old people die without diagnosis of their tuberculosis the lesions have burned out The symptoms if they exist at all are only mild Yet these patients may infect other people No case finding campaign is complete if it neglects the aged These should receive special attention If the findings are negative reexaminations should be conducted regularly Old seemingly inactive fibrosed lesions may be only smoldering and though not progressive may be liberating tubercle bacilli without affecting the activity of the patient

Primary tuberculosis may occur in older persons but most cases of the tuberculosis in the old are benign or chronic

## TREATMENT OF TUBERCULOSIS

*Evaluation of the Tuberculous Lesion — To institutionalize an individual because of* the presence of an x ray shadow which represents a well-stabilized lesion is a serious error It is equally serious to withhold or delay treatment in a patient with a progressive process just because there is no radiologic evidence of activity Evaluation of the tuberculous lesion and the need for treatment therefore call for careful weighing of the evidence presented and decision as to whether the lesions are arrested or are still active and whether progressive or receding

Primary tuberculosis observed most often in children usually requires no treatment The tubercle bacilli allergy reaches its height in from 3 to 7 weeks In approximately 5 per cent of those infected for the first time radiologic evidence and clinical symptoms can be observed Accelerated erythrocyte sedimentation rate slight fever and malaise may be noted at this time but after bed rest these generally disappear If a dense homogenous focus with collateral inflammation is observed radiologically bronchoscopy may indicate whether this shadow results from an atelectasis caused by bronchial obstruction or from a primary focus A shadow cast by a primary focus may last for a few months without sympto-

matic manifestations then slowly resolve In a few children, a lesion may develop that is too small to observe radiologically, but it may later show calcified deposits If the shadow is due to atelectasis, streptomycin therapy is helpful and may prevent development of bronchiectasis, but if the shadow is evidence of a primary focus, unless this process is progressive streptomycin is of no value and might only cause development of streptomycin resistant bacilli and so prevent use of the drug against a subsequent serious tuberculous infection Most of the primary cases resolve spontaneously A child with a primary tuberculosis should be removed immediately from contact with the infecting person and have periodic *x* ray examinations to determine whether an active process has developed

Primary tuberculosis may occur in adults and tuberculous adults should be examined periodically to discover any reactivation or new infection as soon as possible since the success of therapy depends upon the duration of the infection its extent and the promptness with which treatment is initiated

Necropsy evidence and occasional clinical findings show that approximately 25 per cent of all tuberculous persons have had lesions which responded to the natural defense mechanisms of the body without the aid of special therapy In some instances in which cure has been ascribed to a particular type of treatment, recovery has really *been brought about by this natural defense* mechanism Patients with old calcified primary tuberculous complexes those with apical, nodular fibrotic areas and those with adhesions and scarring caused by old pleurisies are not candidates for hospitalization These patients should be warned however that careful periodic radiologic examinations are necessary for assurance that the arrest of the process has continued since reactivation may occur whenever resistance is lowered On the other hand treatment is mandatory for every patient with symptoms of pulmonary tuberculosis or roentgenologic evidence of unstable disease The importance of treatment in the subclinical stage cannot be overemphasized, for, if delayed until symptoms are well defined, the patient may lose his chance of recovery

Treatment may consist of bed rest alone or in combination with collapse therapy antimicrobial therapy, or surgical excision Prolonged bed rest is an absolute requirement All other treatments are to be considered adjunct therapy Whether bed rest shall be complete or modified depends upon the type of the infection its severity, and the emotional response and cooperativeness of the patient Usually, the initial treatment is complete bed rest, modified as the symptoms of the patient recede The objective of treatment is not only to secure arrest of active progressive lesions but also to prevent complications, such as hemoptysis dissemination of a caseous lesion, and cavity formation

*Bed Rest* —Bed rest when complete requires rest in bed for the entire 24 hours without bathroom or dining room privileges Before the cure is instituted the patient should arrange his personal and family affairs so that complete relaxation of body and mind can be assured The duration of the treatment is largely dependent upon the patient s cooperation For this reason confidence in his physician and belief in his ultimate recovery must be established at once

Whether the patient shall enter a sanatorium or be allowed to remain at home is often a difficult problem to decide Strict isolation is necessary for a patient whose sputum is positive for tubercle bacilli, and *this is difficult except in a sanatorium* Those with noncommunicable disease may remain at home if complete cooperation of patient and family can be obtained Consciously or unconsciously a patient at home will ignore some of the rules designed for his cure In a sanatorium he eats sleeps rests on schedule He observes others suffering from the same disease and the strict discipline becomes less onerous as he watches other patients who adjust themselves to the routine and reap its benefits He notes too the continued ill health of those who fail to cooperate

Bed rest is based upon physiologic principles During rest in bed the motion of the lungs is decreased approximately 75 per cent the lung volume is reduced by 20 per cent and the accompanying decrease in body metabolism reduces the

amount of blood flowing through the parenchyma so that the absorption of toxic products is lessened with alleviation of symptoms This decrease in blood supply reduces the oxygen supply to the lung so that carbon dioxide accumulates in the tissues Since the tubercle bacilli depend upon a constant supply of oxygen for their growth their increase is limited in the presence of the augmented carbon dioxide In addition in the supine position the power of the cilia to expel bacteria and exudates from the bronchi is increased The healing process of fibrosis is enhanced by decrease in the tension of the affected areas This is brought about by reduction of lung volume by lymph stasis and by tissue ischemia and results in increased local tissue defense and repair

The predilection of tuberculosis for the upper lobes of the lungs is another reason for prescribing bed rest According to a theory of Dock's the flow of arterial blood is greatly restricted at the apices of the lungs of most persons when they are in the upright position since the pressure of the column of blood from the right ventricle to the apices of the lungs is equal to or greater than the mean arterial pressure in the pulmonary arteries In the upright position tissue fluid or lymph is not produced by infiltration in the apical area since a pressure of nearly 15 mm Hg is required to overcome the difference in osmotic pressure between the plasma and the pulmonary tissue fluid As a result of the decreased blood flow to the apices of the lungs the increase of carbon dioxide to the alveoli in this area and the removal of oxygen from them will be at a minimum Tubercle bacilli reaching the apical tissues therefore will be in an optimal atomsphere for support of their metabolism As long as the patient remains upright the pulmonary arteries can bring few antibodies to the apical areas and the removal of bacterial products by the lymph or their dilution in the blood is almost inhibited Hence the removal of bacteria by the lymph during the patient's waking hours and the replacement of bacteria with antibodies from the blood are both practically suspended These facts offer some explanation of why tuberculosis gains a foothold in active lively young persons and in adults whose hours of sleep and rest are minimal During the long hours of activity the bacilli enjoy optimal growth conditions For these reasons the ideal treatment of early apical lesions is complete recumbency for most of the 24 hours Assuming any other position for any but minimum periods interferes with the postural management of tuberculous lesions

*Effective Use of Bed Rest*—To give the lung the maximum amount of rest the patient lies on the affected side in order to reduce the pulmonary movements To facilitate necessary drainage the patient may be kept in the Trendelenburg position throughout the day or for 3 hours in the morning and from 3 to 4 hours in the afternoon This position relieves the diaphragm from the downward pull of the abdominal organs decreases the size of the thoracic cavity and reduces the suction effect of the intrapleural negative pressure The mobility of the upper third of the lung is thereby increased and good drainage induced through the bronchi of the diseased area If the Trendelenburg position is not used the patient lies on the affected side most of the time turning on the unaffected side for 10 minutes every third or fourth hour to facilitate drainage Changing of posture it should be noted particularly if the disease is acutely active should be accomplished with the least possible disturbance of the lungs and the least possible expenditure of energy To decrease the movements of the lung further weights are sometimes placed on the chest directly over the lesion of the upper lobe At first half pound bags of shot are used heavier and heavier bags are then gradually substituted for these till the maximum weight the patient can comfortably support is reached

Some physicians prescribe a modified bed rest which allows reclining in bed or on a chaise lounge for approximately 20 hours The patient eats his meals in an adjoining room and has full bathroom privileges No rule can be laid down for the type of bed rest required in cases of tuberculosis it must be adjusted to individual requirements Some patients with advanced tuberculosis may be required to lie horizontally relaxed mentally and physically for 24 hours a day 7 days a week every week for years or until the disease is brought under control

Relaxation is the business of the day each hour of the day is so planned as to give the diseased lung the greatest possible amount of rest with the fewest possible interruptions The amount of activity allowed should be mapped out by the physician Unexciting radio programs light reading and light games may help the patient pass the hours without exertion Some authorities believe that a patient who is to remain at home should first spend several months in a sanatorium to acclimate himself to the strict routine necessary for recovery

The emotional reactions of the patient must be taken into consideration in planning his course of treatment. To obtain his cooperation after the first shock of the diagnosis and overcome his hopelessness and antagonistic attitude requires patience and skill. The patient must be persuaded that if he receives the right care and is cooperative, he can live long and usefully.

Except for the antibiotics, drugs are not usually required in the treatment of tuberculosis, though they may be indicated for the treatment of complications. Sedatives should not be administered for emotional upsets, since they disturb the cough reflex and cause a retention of secretions.

*Symptomatic Treatment of Tuberculosis.—Cough.*—Cough in pulmonary tuberculosis is a purposeful physiologic reflex response to irritation or pressure within the respiratory tract and a mechanical aid to the evacuation of exudative substances within the bronchial tree. For this reason productive cough is a useful process and should not be unduly suppressed. The value of a productive cough in conjunction with postural drainage should therefore be made plain to the patient. Coughing may become habitual because of nervousness, or the patient may be overanxious to produce sputum and overexert himself.

A cough routine can be developed for thorough evacuation of the sputum in the morning or after meals with little or no coughing the rest of the day. An unproductive cough should be suppressed since it only causes irritation and exhaustion. A wracking cough may be controlled by hot drinks in the morning or by a dose of from 15 to 20 drops of aromatic spirits of ammonia before breakfast and complete rest for half an hour before and after that meal. Codeine sulfate $\frac{1}{4}$ gr every 4 hours or dilaudid hydrochloride $\frac{1}{32}$ gr every 4 hours may also give relief as may demerol in 50 milligram doses given orally after meals and at bedtime. The danger of addiction should be borne in mind.

Snug chest binders adjustable in front may prove helpful. If there is a large cavity and the secretion is excessive, instruction in assuming a proper position in bed for drainage of the bronchial tree a number of times a day will relieve the patient of cough during the intervening periods. If the clearing out of the exudation is unsatisfactory, elevation of the foot of the bed 8 or 9 inches may bring adequate evacuation. If the sputum is too tenacious to be raised without undue effort, sipping hot milk, water or lemonade may afford relief. The use of a humidifier or the inhalation of steam is also helpful. When bronchial spasm is present, antispasmodic mixtures may be used. Expectorant drugs may be given to raise the sputum if all other measures fail. Banyai has found that inhalation of a mixture of 10 per cent carbon dioxide and 90 per cent oxygen changes an unproductive cough into a useful one, decreasing the thickness and tenacity of the sputum and reducing the need for other expectorants. Its use is contraindicated after pulmonary hemorrhage or when severe emphysema, acute fibrinous pleurisy, pleurisy with effusion or hypertension is present.

If the cough is aggravated by a secondary infection such as bronchitis, bronchiectasis, or lung abscess, aerosol penicillin may prove helpful. Where cough has been found referable to tuberculous lesions of the larynx or trachea, streptomycin has been used with striking effect.

*Pain.*—Pain is rarely an important symptom, but a pleuritic pain may become distressing and retard recovery. The use of counterirritants like mustard plasters or painting the skin over the affected area with iodine or applications of menthol or oil of wintergreen ointments may be helpful. Strapping with adhesive tape recommended by some may make the patient uncomfortable and dyspneic. Well-fitting chest binders are more effective. Pain in the lower back may be the result of being propped up in bed or of muscular strain from a sagging bed. A board beneath the mattress or a firm mattress may lessen the discomfort. Aspirin, empirin or codeine may be given if required. An injection of 10 cc. of a 1 per cent procaine solution with 1:25,000 epinephrine hydrochloride into the skin, thoracic wall or parietal pleura has been recommended.

Laryngeal pain is a common complication of pulmonary tuberculosis, the laryngeal

tuberculosis is caused by infective sputum or by bacilli carried to the larynx by the blood stream. The cooperation of the patient must be secured in this case by explaining the need for complete silence to give the larynx a rest. The patient may communicate by writing or, when absolutely necessary, by whispering. Cocaine pastilles may be sucked to relieve the pain or a solution 1 to 5 per cent cocaine used as a spray, but the latter entails some danger. Sulfonamide powder (5 to 10 gr.) blown into the larynx twice a day has proved effective in some cases. Beckman recommends orthoform emulsion self-administered through a Yankauer laryngeal medicator or iodoform weighted with a small amount of talcum. The latter is for insufflation but is preceded by a spray to prevent coughing. In some instances the discomforting pain has been dispelled by gargling with bicarbonate of soda in water on awakening in the morning.

*Hemoptysis.*—The fright of the patient following hemoptysis must be allayed by assurance that it is not a dangerous symptom. Slight streaking of sputum does not require treatment, but moderate bleeding demands absolute rest with partial propping up in bed so that the blood can flow out of the mouth. All movements should be restricted. Coughing up of clots may prevent obstruction of the bronchi; on the other hand, severe coughing may lead to aspiration of contaminated blood into healthy alveoli. Anemia resulting from loss of blood can be treated by administration of ferrous sulfate or gluconate, 12 to 15 gr., with meals. Blood transfusion may be advisable. Restriction of the diet to cold food and drinks for a while has been suggested. If the prothrombin content of the blood is low, vitamin K may be helpful. Enemas or cathartics to prevent straining at stool are advised. Narcotics, particularly morphine, should not be used to the point of inhibiting the cough reflex. In persistent or repeated severe hemorrhage, artificial pneumothorax or pneumoperitoneum may be indicated in order to relax the lung. This should be delayed for a few days, however, until the air passages are free from accumulated blood; this will diminish the chance of the development of the acute pneumonic reactions and serofibrinous pleurisy that may follow pneumothorax. If pneumothorax and pneumoperitoneum fail, other forms of collapse therapy should be considered, such as extrapleural pneumothorax or diaphragmatic paralysis.

*Fever and night sweats* resulting from inadequate rest, poorly ventilated rooms or too much clothing seldom occur after the patient is under hospital routine. Absolute bed rest, fresh air and mental relaxation usually produce remission of these symptoms. Fever wasting the strength of the patient may be relieved or prevented by administration of aspirin or phenacetin, 5 to 10 gr. (0.32 to 0.65 Gm.), acetanilid, 3 gr. (0.2 Gm.), or aminopyrine, 5 gr. (0.32 Gm.). Atropin sulfate, 1/200 to 1/100 gr. (0.32 to 0.65 mg.), or agaricin, ½ gr. (30 mg.), taken not more than three times in 24 hours may be used for persistent night sweats, but the results are frequently disappointing. Some prefer camphoric acid, 20 to 30 gr. (1.3 to 2 Gm.), an hour or two before the sweating usually occurs. An alcohol rub or a bath with tepid water containing 15 gr. (1 Gm.) of alum may prevent attacks of sweating.

*Digestive upsets* and *anorexia*, particularly before proper adjustment to the regimen is made, are not uncommon symptoms in tuberculous patients. Complete rest just before and after meals with stimulation of the appetite by protamine zinc insulin, tinctures of nux vomica, gentian or cardamon has been suggested as helpful treatment. Sodium bicarbonate, 15 gr. (1 Gm.), or 2 cc. of aromatic spirits of ammonia dissolved in warm water may relieve postprandial distress; if these bring no relief, dilute hydrochloric acid may be of value. Nausea may be relieved by application of an icebag to the abdomen. Use of a stomach tube will relieve vomiting. Calcium salts taken orally, calcium gluconate given intramuscularly, or either of these administered intravenously may be used to relieve diarrhea unless this is due to extensive intestinal ulceration. It may be due to dietary factors. Investigation must be made as to the cause of any serious diarrhea, since it may result from general toxemia

hypochlorhydria, or intestinal tuberculosis Amyloid disease may cause the diarrhea in cases of long-standing cavitation and mixed infection

Enteritis is generally the result of a general lowering of resistance and is difficult to control when once established Milk in excess should be avoided and meals should be small in bulk Calcium gluconate (10 cc of a 5 per cent solution) given intravenously has been recommended, as have oral doses of calcium Pain in enteritis may be relieved by tight bandaging of the abdomen

Constipation may be relieved by proper diet and training in regular bowel habits Mild laxatives are sometimes indicated or from ½ oz to 1 oz of mineral oil at bedtime One or two glasses of water half an hour before meals may be helpful

A well balanced diet of from 2500 to 3500 calories will usually prove adequate for tuberculous patients It has been well said that malnutrition is a result rather than a cause of tuberculosis and is not an evidence of metabolic disturbance For this reason, restoration of normal weight in the tuberculous patient is best accomplished by properly treating the tuberculosis Overfeeding is unnecessary, and overweight may tax the pulmonary function The patient should have three meals a day without between meal feeding unless he is unable to take sufficient food at meal time The forcing of milk on a patient is not recommended it may upset the digestion in some and may be distasteful to others Milk nevertheless is a most desirable food and several glassfuls should be included in the daily diet

The food given the tuberculous patient should be attractive and palatable The vitamin intake particularly the intake of vitamins A and C deficiency in which causes pathologic changes in the mucous membranes that may lead to bronchial occlusion should be carefully regulated A complication like bronchial occlusion may be prevented by giving the patient cod liver oil (⅓ oz daily) supplemented with orange or tomato juice (2 to 4 oz after meals) The cod liver oil should be made as palatable as possible Vitamin C may be administered as synthetic ascorbic acid

*Insomnia* —Unadjusted nervous tuberculous patients may suffer from insomnia A tactful discussion of the cause of their nervousness and the need for its control, with assurance that sleeplessness is the result of habit, may relieve the insomnia Visitors in the evening, or visitors who stay too long or talk of disturbing things may be a cause of the upset A comfortable bed is a necessity Proper ventilation of the room, gentle sponging and massage and a hot drink at bedtime may bring a degree of comfort Sedatives, if required, should be discontinued as soon as possible

*Psychotherapy* —Psychologic management of the tuberculous patient is an important part of treatment for the cooperation of the patient in following the prescribed regimen and his belief in the efforts of the physician and in the hope of cure are necessary for recovery The patient should be told the nature of his disease and the possible length of his illness The need for long continued and absolute rest in bed should be explained to him He must be made to understand that there is no short cut to recovery that recovery depends on following without question a regimen that has cured others And, since mental and emotional as well as physical relaxation is imperative, the patient s psychologic maladjustments should be corrected

A patient with minimal disease may require no more treatment than bed rest His progress will be determined by clinical laboratory and radiologic studies Changes in temperature, pulse rate and sedimentation rate, weight maintenance and the appearance or nonappearance of tubercle bacilli in the sputum or gastric contents will indicate the results of bed rest Early abatement of symptoms may indicate improvement but until the sputum becomes negative and *x* ray findings indicate a healing process strict bed rest must continue Asymptomatic patients with active minimal lesions require from 6 to 12 months of continuous rest if the lesions are extensive the patients require from 18 months to 2 or more years of such rest It has been noted that improvement as a result of bed rest is greatest in the first month and that the improvement gradually decreases with time

When sufficient clinical improvement is evident the patient may be allowed to sit up for 15 or 30 minutes daily the amount of time being increased every 2 or 3 weeks The first modification of complete bed rest usually consists in allowing one or two trips to the bathroom wheelchair trips to the treatment room and minor occupational therapy in bed for not more than one hour daily Occupational therapy is allowed for 2 hours when the patient has received full bathroom privileges and he is occasionally allowed to attend church services and movies and engage in other recreations afforded in the sanatorium The patient is fully dressed on these occasions The patient walks to the treatment rooms and to the bathroom and takes his own bath Another privilege is reading studying and listening to the radio during the morning rest hours The patient next becomes ambulatory is fully dressed makes his own bed keeps his room clean and begins supervised activities for 1 to 2 hours daily These hours of activity are gradually lengthened All through these periods of increasing activity up to the time of discharge the patient obeys the rules of absolute bed rest between 1 00 P M and 3 00 P M and lights-out at 9 00 P M The length of time between each period of increased freedom varies with each patient and is entirely dependent upon evident progress in recovery

Often bed rest is sufficient for cure Mitchell reported that of 289 patients with uncomplicated minimal pulmonary tuberculosis followed for 7 or more years after discharge only 37 per cent had one or more reactivations Except for 3 per cent who died and 4 per cent who remained chronically ill all were well and working

Patients who do not respond satisfactorily to complete bed rest require additional therapy such as antimicrobial therapy collapse therapy or surgical intervention or a combination of these

*Antimicrobial Therapy* —The antibiotics although neither a substitute for bed rest nor a substitute for collapse therapy or surgical treatment have opened a new era in the treatment of pulmonary tuberculosis Removal of even a segment of a lung was a dangerous procedure before the advent of the antibiotics but as now used preoperatively and postoperatively these agents have made lung surgery a common method of therapy (See page 985)

*Mechanical and Surgical Therapy of Tuberculosis* —The purpose of collapse therapy is to promote healing of the tuberculous process through relaxation of the lung The volume of the lung is thereby decreased and its physiologic activity lessened as is shown by reduction in ventilation vital capacity and oxygen uptake together with decreased flow of blood and lymph Despite prolonged bed rest a cavity may refuse to heal but when the elastic pull on the cavity walls is relieved by collapse of the lung these walls come together and healing is made possible The parts under the greatest elastic tension recoil the most this brings about shrinkage of the cavity and scar retraction complete closure may follow Meanwhile decreased lymph flow diminishes transport of toxic material from the diseased areas into the general circulation and lessens the toxic symptoms The attendant relative tissue anoxia and lymphostasis apparently enhance fibrosis and diminished oxygenation of the tissues produces conditions unfavorable to growth of the tubercle bacilli

*Artificial pneumothorax* like pneumoperitoneum and phrenic paralysis are reversible processes wheras thoracoplasty is irreversible Each has its place The popularity of artificial pneumothorax has somewhat waned since the possibilities of the other methods have become defined

Indications for the use of pneumothorax are (1) a progressive tuberculous process (2) continued positive sputum (3) cavitation and (4) uncontrollable hemorrhage A tuberculous spontaneous pneumothorax may be converted into a controlled pneumothorax The success of artificial pneumothorax depends to a large degree upon careful case selection In some cases relaxation of the lung sets up a check valve mechanism in the draining bronchus by narrowing the lumen so that the cavities do not close and may even become enlarged Cavities with thick fibrous walls do not respond to this procedure The best results are achieved in small cavities with infiltrations

that are predominantly nodular or bronchopneumonic. Cavities in the upper lobes without extensive exudation or caseation give excellent response. Extensive pleural fibrosis or adhesions will prevent successful pneumothorax. In the latter case intrapleural pneumonolysis should be undertaken to divide the adhesions between the pleural layers. Otherwise artificial pneumothorax must be abandoned.

An active tuberculous process in the opposite lung is not a contraindication to pneumothorax. A minor lesion in the opposite lung may heal spontaneously. Bilateral pneumothorax is often successful but care must be taken to prevent respiratory embarrassment. Refills may occasionally be given at the same time in well-established and well tolerated bilateral cases.

Artificial pneumothorax is contraindicated in the presence of very large cavities located at the periphery of the lung, cavities with rigid walls, tension cavities, bronchial tuberculosis with severe ulcero granulomatous involvement or fibrostenosis of the bronchial lumen, bilateral miliary tuberculosis, predominantly fibrous tuberculosis of long duration with contraction of the corresponding hemothorax, extensive bilateral tuberculous disease and pronounced pleural thickening. Other contraindications are empyema, bronchial asthma, decompensated heart disease, amyloidosis, and hopeless prognosis. Pregnancy is not a contraindication.

When an early infiltrate spills tubercle bacilli into the surrounding pulmonary tissue, a cavity is formed with an encircling bronchopneumonia. While this acute tissue reaction about the tuberculous focus remains active, interference is contraindicated. Absolute bed rest and streptomycin therapy constitute the only recommended treatment. Collapse therapy at this time may prove harmful since artificial pneumothorax is almost always followed by an acute pleurisy and the collapsed areas begin to organize and fibrose. Bed rest and streptomycin will tend to clear out the exudate and decrease the size of the cavity. After the maximum benefit from these measures has been obtained, collapse therapy may be considered. The smaller the cavity is, the more likely is pneumothorax to be successful. If collapse therapy should fail to control the tuberculous process, major surgery must be attempted.

Refills should be continued for from 2 to 6 years or until the cavities are completely closed. If the sputum remains positive after 6 months, this treatment should be discontinued and other collapse therapy substituted.

The most frequent complication is pleural effusion, occurring in approximately 80 per cent of cases. This may absorb spontaneously or may require aspiration. Since the advent of antimicrobial therapy, the previous incidence of empyema in pneumothorax patients (10 per cent) has been substantially reduced by combined streptomycin and PAS administration before the introduction of pneumothorax. Frequent aspiration and thoracoplasty may be required when it occurs. Other complications occasionally observed are air embolism, pleural shock, surgical emphysema, accidental pneumothorax and hemoptysis.

Failure of the lung to re-expand after pneumothorax is discontinued may require decortication of the fibrinous coverings which have accumulated. When peeled off the lung may readily expand.

*Closed Intrapleural Pneumonolysis.*—In many cases of pulmonary tuberculosis adhesions exist between the visceral and parietal layers of the pleura. These may prevent adequate collapse or relaxation of the lung by artificial pneumothorax. In such cases the adhesions should be severed (intrapleural pneumonolysis), after which the lung will usually collapse satisfactorily.

*Phrenic-nerve crush* is the simplest and safest method of collapse therapy and, although considered the least effective procedure, has frequently produced dramatic results. Many tuberculous patients are unfitted for surgical measures and others fail to have adequate collapse following artificial pneumothorax because of pleuritic adhesions. Rather than submit these patients to continued ineffectual pneumothorax or to prolonged bed rest, it may be preferable to attempt collapse by phrenic nerve block.

Permanent paralysis of the diaphragm

was favored in former years today temporary paralysis is preferred The operation may be repeated once or twice a year if necessary, if closure of the cavity and arrest of the disease has been achieved or it may be made permanent in selected cases. Paralysis of the diaphragm may be supplemented by pneumoperitoneum to increase the elevation of the diaphragm and effectiveness of the operation

*Pneumoperitoneum* —Pneumoperitoneum is a simple and safe method of collapsing the lung without causing the complications that follow artificial pneumothorax It may be used in cases considered unsuitable for pneumothorax or thoracoplasty Artificial pneumothorax produces collapse of the lung by direct action of the air in the thorax Pneumoperitoneum on the contrary produces relaxation of the lung by increasing the air pressure under the diaphragm thus causing it to rise high in the chest

When combined with streptomycin therapy pneumoperitoneum has proved a method of choice for patients with bilateral tuberculous disease with fibrotic changes cavitation and marked or moderate exudation In exudative bilateral tuberculous disease that precludes use of pneumothorax and major surgery this combined treatment is often of great value

*Intracavitary suction drainage* as suggested by Monaldi is drainage of a cavity by introduction of a catheter into it through the chest wall It is indicated for patients with large ballooned cavities connected with stenosed bronchi This procedure succeeds in diminishing and sometimes closing cavities

This procedure is advocated in cases in which previous collapse therapy or low vital capacity forbids continued collapse treatment or resection

*Oleothorax* is a procedure now rarely used It consists of instilling a vegetable oil treated with Gomenol or other mild antiseptic into an intrapleural pneumothorax space

*Other Forms of Mechanical Therapy* —Various types of mechanical therapy advocated in the past are rarely used today Such procedures include scalenotomy scalenectomy (division or partial resection of the scalene muscles) open cavity drainage and multiple intercostal nerve paralysis Other methods have been found more effective

Such nonsurgical mechanical aids to immobilization and compression therapy as sand or shot bags hammocks or swings corsets and braces continue to be used Very good results have been reported from the use of the Barach equalizing pressure chamber but because the equipment is expensive it is not generally available The results obtained have been sufficiently favorable to indicate that this method of treating pulmonary tuberculosis is worthy of further study

*Other Forms of Surgical Therapy* —Other surgical procedures for pulmonary tuberculosis than those discussed include thoracoplasty lobectomy pneumonectomy and segmental pulmonary resection Resections are being attended with encouraging results due largely to the use of streptomycin

A thorough knowledge of the physiologic function of the patient s lung and its pathologic affections must be obtained before mapping out a therapeutic program The physician s task does not stop with arrest of the disease it continues with planning the patient s rehabilitation and maintaining constant vigilance against reactivation of his tuberculous process Beyond this lies the equally great task of preventing the spread of tuberculosis This involves early diagnosis and treatment of cases and immunization of the public against the disease in so far as such immunization can be achieved

*Note on BCG Vaccination* —The subject of immunity to tuberculosis though it has been the subject of intensive investigation is still a controversial issue For a critical review of the matter the reader is referred to Rich A *The Pathogenesis of Tuberculosis* Charles C Thomas 1944 and to Lurie Max B Natural and Acquired Resistance to Tuberculosis *Am Jr of Medicine* Vol IX (Nov ) 1950

Many vaccines have been prepared and used from time to time to increase resistance to tuberculosis None have withstood the test of time Vaccination with the Calmette Guerin bacillus holds the greatest interest today Calmette and Guerin cultivated a highly virulent bovine tubercle bacillus (isolated by Nocard from the udder of a tuberculous cow in 1902) on a medium con

sisting of potato cooked in 5 per-cent glycerinated ox bile. After 236 transplantations on this medium, the virulence of the organism was lost for laboratory animals and cattle. Despite the organism's loss of virulence, however, vaccination with this attenuated culture gave cattle considerable protection against virulent infection with bovine tubercle bacilli.

In 1922, Weill Hall was the first to give the vaccine orally to newborn babies of tuberculous mothers. No untoward effects followed its administration. Indeed, in such infants less clinical tuberculosis developed than in unvaccinated infants of tuberculous mothers. BCG mass vaccination first by the oral route and subsequently by the intracutaneous route was soon afterwards used widely in France, the Scandinavian countries, Spain, Russia, and the Balkan States. In the United States vaccination of infants and children with BCG was begun in 1926 in New York City by Park and his associates. This work is still in progress.

One of the most painstaking BCG-vaccination studies in this country has been carried out among American Indians by Aronson and his associates. A report of the outcome of his well controlled work from nine to eleven years after the vaccinations shows that of 1551 BCG-vaccinated Indians only six died of tuberculosis, whereas of 1457 Indians not vaccinated with BCG 38 died of the disease.

It is therefore apparent that though BCG vaccination may not confer complete immunity to tuberculosis, it nevertheless does reduce the mortality rate for tuberculosis among persons exposed to the disease.

Among the many hundreds of thousands of persons to whom the vaccine has been given, there is no evidence of a single death that can be attributed directly to the vaccine. The disaster in Lubeck, Germany (where many infants who supposedly received BCG fell ill—some died of tuberculosis) was apparently due to contamination of the vaccine with virulent tubercle bacilli.

It should be stated that, in the United States and Great Britain, where antituberculosis progress has been outstanding, BCG vaccination is not received with any enthusiasm. Indeed, some authorities in this country (like J. Arthur Myers) are strongly opposed to mass vaccination with BCG.

"The tuberculin reaction," he says, "indicates the presence of sensitivity to tuberculoprotein and has not been demonstrated to be a criterion of immunity. The temporary fixing power of allergic tissue was formerly misinterpreted as indicating immunity. No test has been devised to identify or measure immunity."

*Indications for Use of BCG.*—BCG vaccination is recommended for tuberculin-negative persons, such as nurses, attendants, interns, and others exposed to tuberculous patients or to material containing viable and virulent tubercle bacilli. It is also indicated for use in badly contaminated regions, regions in which social and economic conditions favor the spread of tuberculosis, to protect infants and young adults from infection.

*Contraindications.*—BCG vaccination is not recommended for (1) persons who have a tuberculin-positive reaction, (2) persons suffering from any infectious skin condition (such as impetigo), (3) persons recently vaccinated with smallpox vaccine, (4) persons suffering from pyrexia, malaise, or other subjective symptoms, or (5) premature or underweight infants.

In progressive countries, countries in which efficient health measures have reduced the mortality rate for tuberculosis to a low level, the advantages to be gained from BCG are not likely to be great.—Editor.

## REHABILITATION

Rehabilitation of the tuberculous patient was defined at the Washington Conference on Rehabilitation of the Tuberculous as "any services necessary to render a tuberculous patient fit to engage in a remunerative occupation suitable to health and aptitude." Recovery of the tuberculous patient, therefore, means more than arrest of this disease; it means restoration to a normal life. As Murray has said, "Morally and economically the doctor who takes care of a patient's illness can no longer wash his hands of the problem when the medical condition is cured. His problem must include the restor

ation of the patient to usefulness Establishment of hope and belief in ability to recover must be instilled early in the patient and maintained all through the *long period of treatment*

The seasoning of the convalescent patient to limited hours of work that increase with gain of strength often begins with light suitable work around the sanatorium If *reasonable amounts of work are alloted* this activity promotes a purposeful exercise and helps the patient to begin the readjustment to everyday life

Approximately 50 per cent of the recovered *patients are said to return to their* former jobs either part or full time Others may have done work that would now be too demanding upon their strength and for these vocational guidance may be required *Psychotherapist physiotherapist* social worker and social agencies work together to fit the patient into a new job and find the particular niche he is best fitted to fill The former training of the patient should always be *taken into consideration*

## PROGNOSIS IN TUBERCULOSIS

Prognosis in pulmonary tuberculosis must always be *guarded cure can never* be certain Those with apparent arrest of the disease are subject to reactivation at any time Patients with minimal disease after prolonged bed rest and antimicrobial and collapse therapy *may nevertheless gradually* succumb to the disease The risk of these patients dying within a few years is always greater than that of the rest of the general population This risk is increased manyfold in those with *moderately* advanced tuberculosis whatever treatment is administered For those with far advanced disease the prognosis is always grave

The prognosis depends upon consideration of a number of factors The extent of the lesion at the time therapy is initiated is important According to studies reported life expectancy for patients with early or limited lesions without cavity formation is much better than it is for patients with moderately advanced disease It has been estimated that a third of the latter did not survive after five years until the advent of the antibiotics Those with far advanced disease do not usually survive for more than from 2 to 5 years without special therapy Today with antimicrobial therapy collapse *therapy and radical pulmonary surgery a* surprising number of these seemingly hopeless patients survive

The nature of the lesion also has a bearing on the outcome of treatment Lesions of *the fibroid nodular type tend to respond* well to treatment whereas those of the exudative bronchopneumonic type although they sometimes resolve tend to maintain unresolved caseous cores These are apt to *be sloughed off into the bronchial tree and* disseminate into the surrounding parenchyma Again the size of the cavity has an affect upon the prognosis Cavities over 2 cm in diameter are difficult to obliterate by *collapse therapy* and *unless* arrest of the process can be secured by resection death usually occurs within five years On the other hand a small fibrous cavity may cause a continuously positive sputum *but the patient has a good life expectancy* Cases in which there are very large cavities can rarely be controlled and care of such cases in sanatoria is for relief of the victims symptoms and for the protection of the *public*

The clinical symptoms as Amberson points out likewise serve as a partial index to the prognosis An older person without fever has a better chance of recovery than a *young one with prolonged fever* A patient with a small amount of sputum may have no extension for years whereas a large amount of liquid sputum may indicate early extension Prognosis is better when the tubercle bacilli are scarce this indicating that the cavity walls are not undergoing active necrosis A patient with normal temperature pulse and sedimentation rate has a good outlook Age and race are additional factors affecting prognosis Tuberculosis in the young is more serious than in older persons Recovery from tuberculosis is less frequent in the negro than in the white race

Prognosis is most favorable when diagnosis is made early and treatment is prompt and adequate Once a patient s disease is apparently arrested and he is discharged

sisting of potato cooked in 5 per cent glycerinated ox bile After 230 transplantations on this medium the virulence of the organism was lost for laboratory animals and cattle Despite the organism's loss of virulence however, vaccination with this attenuated culture gave cattle considerable protection against virulent *infection* with bovine tubercle bacilli

In 1922 Weill-Hall was *the first to give* the vaccine orally to newborn babies of tuberculous mothers No untoward effects followed its administration Indeed in such infants, less clinical tuberculosis developed than in unvaccinated infants of tuberculous mothers BCG *mass vaccination first* by the oral route and subsequently by the intracutaneous route was soon afterwards used widely in France the Scandinavian countries, Spain Russia and the Balkan States In the United States, vaccination of infants and children with BCG was begun in 1926 in New York City by Park and his associates This work is still in progress

One of the most painstaking BCG—vaccination studies in this country has been carried out among American Indians by Aronson and his associates A report of the outcome of his well-controlled work from nine to eleven years after the vaccinations shows that of 1551 BCG—vaccinated Indians only six died of tuberculosis whereas of 1457 Indians not vaccinated with BCG *53 died of the disease*

It is therefore apparent that though BCG vaccination may not confer complete immunity to tuberculosis it nevertheless does reduce the mortality rate for tuberculosis among persons exposed to the disease

Among the many *hundreds of thousands* of persons to whom the vaccine has been given, there is no evidence of a single death that can be attributed directly to the vaccine The disaster in Lubeck Germany (where many infants who supposedly received *BCG fell ill—some died of tuberculosis*) was apparently due to contamination of the vaccine with virulent tubercle bacilli

It should be stated that, in the United States and Great Britain, where antituberculosis progress has been outstanding BCG vaccination is not *received* with any enthusiasm Indeed some authorities in this country (like J Arthur Myers) are strongly opposed to mass vaccination with BCG

'The tuberculin reaction he says, 'indicates the presence of sensitivity to tuberculo protein and has not been demonstrated to be a criterion of immunity The *temporary fixing power of allergic tissue* was formerly misinterpreted as indicating *immunity No test has been devised to* identify or measure immunity

*Indications for Use of BCG* —BCG vaccination is recommended for tuberculin negative persons, such as nurses attendants, interns, and others exposed to tuberculous patients or to *material containing viable* and virulent tubercle bacilli It is also indicated for use in badly contaminated regions, regions in which social and economic conditions favor the spread of tuberculosis to protect infants and young adults from infection

*Contraindications* —BCG vaccination is not recommended for (1) persons who have a tuberculin positive reaction (2) persons suffering from any infectious skin condition (such as impetigo) (3) persons recently vaccinated with smallpox vaccine (4) persons suffering from pyrexia malaise or other subjective symptoms or (5) premature or underweight infants

In progressive countries countries in which efficient health measures have reduced *the mortality rate for tuberculosis to a low* level the advantages to be gained from BCG are not likely to be great —Editor

## REHABILITATION

*Rehabilitation of the tuberculous patient* was defined at the Washington Conference on Rehabilitation of the Tuberculous as any services necessary to render a tuberculous patient fit to engage in a remunerative occupation suitable to health and aptitude Recovery of the tuberculous patient therefore means more than arrest of this disease it means restoration to a normal life As Murray has said Morally and economically the doctor who takes care of a patient s illness can no longer wash his hands of the problem when the medical condition is cured His problem must include the restor

## SYPHILIS OF THE LUNG

Congenital syphilis of the lung occurs in the babies of nontreated syphilitic mothers such infants are usually stillborn or die early Their lungs show smooth white areas containing massive or scattered round-cell infiltration and fibrosis and an arrested pulmonary development which makes life impossible (White pneumonia)

Of the two forms of acquired pulmonary syphilis—the fibrinous and the gummatous the latter can be diagnosed with more certainty In the gummatous areas usually located in the middle or lower portions of the lung are grayish nodules with or without caseation but without formation of cavities unless the lesion breaks down The gummatous lesions may be found as masses of scar tissue with fibers radiating throughout the adjoining area the lesions are most marked in the hilar region and extend along the course of the bronchus and vessels The fibers here are finer than those of the usual pulmonary fibrosis and penetrate between the lobules and extend to the periphery of the lung

Acquired syphilis may affect the lung in the secondary or tertiary stage with few if any clinical manifestations or there may be a long history of disease with various symptoms none of them pathognomonic Often the lesions are discovered only during routine x rays of the chest of patients complaining of disease in other organs

*Symptoms and Signs*—In some patients there are cough sometimes with mucopurulent or bloody sputum loss of weight dyspnea and chest pain but there is little or no fever The physical signs may indicate consolidation of the lung tissue with resultant dullness to percussion râles diminished breath sounds and bronchial breathing if there is obstruction of the bronchus Contraction of the lung may cause displacement of the intrathoracic contents The patient may or may not have a history of syphilis in other organs and a positive Wassermann or Kahn test

*Diagnosis*—The diagnosis may be suspected if there is response to antiluetic therapy Bronchoscopic examination is helpful in indicating the extensiveness of

## SYPHILIS OF THE LUNG

*Congenital syphilis of the lung* occurs in the babies of nontreated syphilitic mothers such infants are usually stillborn or die early Their lungs show smooth white areas containing massive or scattered round-cell infiltration and fibrosis and an arrested pulmonary development which makes life impossible (White pneumonia)

Of the two forms of acquired pulmonary syphilis—the fibrinous and the gummatous the latter can be diagnosed with more certainty In the gummatous areas usually located in the middle or lower portions of the lung are grayish nodules with or without caseation but without formation of cavities unless the lesion breaks down The gummatous lesions may be found as masses of scar tissue with fibers radiating throughout the adjoining area the lesions are most marked in the hilar region and extend along the course of the bronchus and vessels The fibers here are finer than those of the usual pulmonary fibrosis and penetrate between the lobules and extend to the periphery of the lung

Acquired syphilis may affect the lung in the secondary or tertiary stage with few if any clinical manifestations or there may be a long history of disease with various symptoms none of them pathognomonic Often the lesions are discovered only during routine x rays of the chest of patients complaining of disease in other organs

*Symptoms and Signs*—In some patients there are cough sometimes with mucopurulent or bloody sputum loss of weight dyspnea and chest pain but there is little or no fever The physical signs may indicate consolidation of the lung tissue with resultant dullness to percussion rales diminished breath sounds and bronchial breathing if there is obstruction of the bronchus Contraction of the lung may cause displacement of the intrathoracic contents The patient may or may not have a history of syphilis in other organs and a positive Wassermann or Kahn test

*Diagnosis*—The diagnosis may be suspected if there is response to antiluetic therapy Bronchoscopic examination is helpful in indicating the extensiveness of

bronchial involvement and in ruling out other conditions

Response to antiluetic therapy does not necessarily indicate syphilis since improvement may be due to the healing of other pulmonary conditions However, these other pulmonary diseases will recur and will not be affected by a second course of antisyphilitic treatment If continued treatment of this type brings abatement of symptoms, *syphilis seems indicated, especially if* the radiologic evidence has disappeared and the patient is feeling better But unless the *T pallidum* is found in the lung tissue the diagnosis of pulmonary syphilis is not certain

## PULMONARY FIBROSIS

Pulmonary fibrosis represents the reparative process following any injury to the lung parenchyma of sufficient severity to cause actual destruction of tissue Fibrosis has *long been recognized as the sequela of a wide* variety of diseases but our understanding of the underlying pathology has been extremely meager and for the most part, limited to quantitative rather than qualitative distinctions Recently Spain has called attention to the several distinctly different patterns of pulmonary fibrosis His studies indicate that the pattern and the distribution of the fibrosis are more closely correlated with the clinical manifestations than is the degree of the fibrosis

*Bronchiolar Fibrosis* —Various inflammatory processes among them acute and chronic bronchitis, diffuse bronchiolectasis, asbestosis phosgene poisoning and diffuse *endobronchial tuberculosis*, exert their primary destructive effect on the bronchi and bronchioles If the process is severe enough healing is associated with the *deposition of* sufficient fibrous tissue in and around the bronchiolar wall to produce narrowing of the lumina and obstructive emphysematous changes distally Since the basic pathology is usually diffuse the emphysema is characteristically generalized A significant reduction in vital capacity results and cor pulmonale is rather frequent

*Interstitial Fibrosis* —Certain diseases all of them rare tend to fibrosis of the interstitial tissue of the lung A classic example is idiopathic pulmonary fibrosis characterized by a startling degree of widespread hyperplasia of the interstitial connective tissue Similar changes are encountered in berylliosis in bauxite poisoning and occasionally, in scleroderma In contrast to bronchiolar fibrosis, the altered physiology here is respiratory not ventilatory for there is no emphysema or increase in the residual air but instead, a diminished $O_2$-$CO_2$ exchange due to fibrous deposition between the alveoli and pulmonary capillaries Decrease in the pulmonary vascular bed from fibrosis leads not infrequently to cor pulmonale

*Parenchymal Fibrosis* —This is the most *common type of pulmonary fibrosis* encountered It may follow a wide variety of diseases such as unresolved pneumonias (including Friedlander s) mycotic diseases of the lung tuberculosis silicosis pulmonary infarction radiation pneumonitis and lipoid pneumonia Both bronchial tree and lung parenchyma are *obliterated so that function* in the involved portion of the lung is completely lost Compensatory emphysema in the remainder of the lung is the normal sequence of events yet is generally not severe enough to cause symptoms Cor pulmonale does not usually occur

*Pulmonary Vascular Fibrosis* —Primary fibrosis of the pulmonary arterioles is uncommon most cases being secondary to the pulmonary hypertension accompanying generalized emphysema The increased resistance to blood flow through the pulmonary *bed places a strain on the right ventricle* a strain eventually leading to cor pulmonale

## IDIOPATHIC FIBROSIS

Idiopathic pulmonary fibrosis (diffuse interstitial fibrosis) is a rare pulmonary disease of a gradually progressive character associated with a tremendous amount of hyperplasia of the interstitial pulmonary connective tissue. The etiology is unknown but the disease is probably of virus origin. The clinical course is marked by severe dyspnea, chronic cough and cyanosis in association with minimal lung findings on physical examination. Death is inevitable for no satisfactory treatment has as yet been devised. However, it may be that the disease occurs in localized form; if so there must be many undiagnosed cases from which the patient recovers.

## PNEUMOCONIOSIS

Pneumoconiosis is largely an occupational disease since in most cases it results from prolonged inhalation of small particles of dust, usually silica, in the atmosphere of mines and industrial plants. It has been estimated that approximately 5 per cent of those who work in this country have been exposed to dust diseases; of these 10 per cent or about a fourth of a million workers have been affected. Silica dust, the chief agent in pneumoconiosis, is inhaled from the air by everyone, and at autopsy is found mottling the parenchyma of the lungs, the degree of mottling depending on the individual's degree of exposure to the dust (the lungs of coal miners, for example, are almost black). A mild pneumoconiosis exists unsuspected in many inhabitants of manufacturing cities where the atmosphere is filled with smoke and dust. A study made in Chicago in 1941 showed that on the average 55 tons of dust per square mile fell from the air each month. Dust storms may also cause considerable deposits of dust particles in the lungs. However these deposits are not disabling although they occasionally lead to acute bronchitis or to asthmatic attacks. It has been calculated that a worker must be exposed to silica dust for from 15 to 20 years and inhale between 15 and 20 million silica particles per cubic foot of air before pneumoconiosis is established.

Pneumoconiosis, which is manifested by a pulmonary fibrosis, not only is the cumulative effect on a susceptible worker of long exposure to silica dust in the atmosphere but is also dependent for its development on the size and composition of the silica particles and on the presence of other respiratory conditions before or during exposure to the atmosphere containing the particles. Since disease due to industrial dust is common and workmen's compensation laws and other legal aspects of the problem require accurate estimates of the degree of disability it causes, the injurious effect of industrial dust is of great concern to physicians. Medicine and industrial management are both trying to find ways to lower the concentration of industrial dust and make the dust itself innocuous to the worker.

Most of the affected workers are middle-aged men who have been employed continuously in a dust laden atmosphere and have gradually accumulated disabling masses of dust particles in their lungs. The illness may be precipitated by a concurrent pulmonary disease or by factors due to the aging process such as arteriosclerosis, cardiovascular disease, obesity, and skeletal changes. These factors must be taken into consideration both in treating the disease and in estimating the amount of disability of occupational origin. One employee, for example, may continue to work making light of a very real disability; another only slightly affected may become emotionally unfit to work. Diagnosis of pneumoconiosis is not simple and often requires expert scientific

study before liability of the employer can be determined

## SILICOSIS

Various nonsilicous inorganic and organic dusts cause either a pneumoconiosis or some other pulmonary affection but the inorganic dusts containing silica are responsible for most of the cases recognized as pneumoconiosis The symptoms of pulmonary fibrosis and its complications occurring in silicosis are typical of most other forms of the disease and in fact of pulmonary fibrosis resulting from any pulmonary affection

Silicosis occurs among workers in many industries, including sandblasting coal mining stone crushing sandstone industries metal grinding pottery-making tunnel building, the manufacturing of abrasive soaps and powders and metal mining

*Pathogenesis* —No form of pneumoconiosis can develop unless the individual is directly exposed to a dust laden atmosphere for a considerable length of time Furthermore not all workers so exposed will develop the disease A third important fact is that before they can be considered dangerous to health the dust particles must be small enough to enter the terminal bronchioles No particle more than 10 microns in diameter can enter the alveoli About 75 per cent of the particles found in the alveoli are less than 3 microns in diameter these are the most dangerous particles

Little of the dust that is inhaled reaches the lungs The narrowness of the nostrils the coarse nasal hairs that trap the dust as it is inhaled and the nasal secretions that wash out the dust particles serve as a protecting mechanism along with the ciliated epithelium of the trachea which with an escalator movement turns the inhaled particles back into the pharynx whence they are expectorated or swallowed

When the particles enter the alveoli the self-cleansing system is activated the phagocytes of the alveolar walls engulf the particles and deposit them in the lymph stream But the phagocytes and lymph channels soon become overloaded then the dust particles block the lymph channels and a series of "dust depots" are formed in the air spaces

As this obstruction in the lymph nodes increases with continued inhalations of dust the pulmonary surface is covered with lesions, the lymphatic vessels being surrounded by beadlike fibrous tissue These formations coalesce to form a massive fibrosis Necrosis and cavitation eventually develop as a result of the decreased blood supply following extensive fibrosis Emphysema is a usual complication but other conditions may develop, such as abscess, spontaneous pneumothorax, pulmonary artery thrombosis hemorrhage adhesive pleurisy, and atelectasis all conditions which follow in the wake of any extensive pulmonary fibrosis

Whether the fibrosis is due to a chemical change in the silica particle as Gardner and many others believe, or to an inflammation caused by the hardness and sharpness of the dust has not been proved * Mayer and Rappaport point out however, that, though the hardness of quartz dust causes inflammation the comparable hardness of emery dust does not The degree of fibrosis depends on the degree of silica dust accumulation, but once nodulization begins, it is progressive A tuberculous process develops in a great many cases

The pulmonary fibrosis of silicosis is not always nodular it may be diffuse Fibrosis following inhalation of silica dust in quarries mines and potteries or any sandblasting industry, tends to be nodular in type characteristic whorled nodules being scattered over the lungs Diffuse fibrosis is found in anthraco-silicosis siderosilicosis, and other mixed silicoses resulting from coal or ore mining or in the diatomaceous earth industry Dust granulomas occurring as the alveolar walls are thickened by infiltration of lymphocytes plasma cells, and giant cells and formation of a fibrous reticulum are not uncommon

Nodular fibrosis contrary to general opinion is less damaging than diffuse fibrosis even in the milder grades since even the slight thickening of the alveolar septa over

* The fibrous response to crystalline dusts (silica etc ) depends on their being piezoelectrically active For discussion of this hypothesis see Silas M Evans M D and Robert L Kascht M D The Pathogenesis of Silicosis The Penna Med Jr Vol 52 Number 14 November 1949 —EDITOR.

diffuse areas greatly diminishes the breathing surface whereas nodular fibrosis however extensive promotes a compensatory emphysema Hence in early cases of diffuse fibrosis the clinical symptoms are out of proportion to the roentgenologic findings *It is possible to distinguish between a tuberculosilicosis* and a silicosis with tuberculosis the former exhibiting the characteristics of silicosis and the latter those of tuberculosis but they may develop simultaneously

gross fibrosis resulting from chronic tuberculous infection This process extends over many years The tuberculous infection may occur early or in very rare cases not at all

The onset of the disease is insidious and symptomless and develops slowly over a *period of years The earliest symptom is* dyspnea on exertion a dyspnea that increases as the disease progresses Another symptom is a dry hacking and nonproductive cough Later as tuberculosis develops

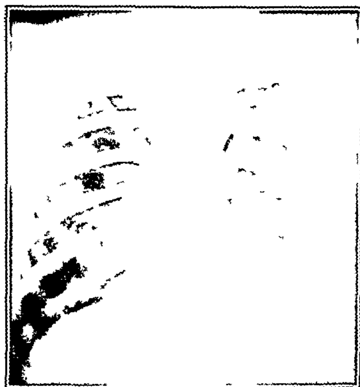

FIG 157 —Silicosis

the cough is accompanied by sputum mixed *with blood and is distressing* There is little pain unless pleurisy develops Chest examination reveals few if any signs at any time and those found are characteristic of any lung infection There may be a slight alteration of chest sounds with shortening of the inspiration phase and a few dry rales and later restriction of movement of the diaphragm and chest walls In the early stages of the disease radiographic examination shows only exaggeration of hilar markings but as the disease progresses shadows

In addition to the common tuberculous *complication of pneumoconiosis nonspecific* infectious complications may arise as a result of incompletely resolved bronchopulmonary lesions Recurrent infections may lead to pneumonitis and chronic abscess formation

*Symptoms and Diagnosis* —Three phases of silicosis have been differentiated (1) the bronchial phase characterized by dry bronchitis or bronchiolitis (2) the nodular phase characterized by small collections of lymphoid tissue in the lung and by fibrosis and (3) the infective phase, characterized by

study before liability of the employer can be determined

## SILICOSIS

Various nonsiliceous inorganic and organic dusts cause either a pneumoconiosis or some other pulmonary affection but the inorganic dusts containing silica are responsible for most of the cases recognized as pneumoconiosis. The symptoms of pulmonary fibrosis and its complications occurring in silicosis are typical of most other forms of *the disease and in fact of pulmonary fibrosis* resulting from any pulmonary affection.

Silicosis occurs among workers in many industries including sandblasting, coal mining, stone-crushing, sandstone industries, metal grinding, pottery-making, tunnel-building, the manufacturing of abrasive soaps and powders, and metal mining.

*Pathogenesis*.—No form of pneumoconiosis can develop unless the individual is *directly exposed to a dust laden atmosphere* for a considerable length of time. Furthermore not all workers so exposed will develop the disease. A third important fact is that before they can be considered dangerous to health, the dust particles must be small enough to enter the terminal bronchioles. No particle more than 10 microns in diameter can enter the alveoli. About 75 per cent of the particles found in the alveoli are less than 3 microns in diameter; these are the most dangerous particles.

Little of the dust that is inhaled reaches the lungs. The narrowness of the nostrils, the coarse nasal hairs that trap the dust as it is inhaled, and the nasal secretions that wash out the dust particles serve as a protecting *mechanism along with the ciliated* epithelium of the trachea, which with an escalator movement turns the inhaled particles back into the pharynx, whence they are expectorated or swallowed.

When the particles enter the alveoli, the self cleansing system is activated: the phagocytes *of the alveolar walls engulf the particles* and deposit them in the lymph stream. But the phagocytes and lymph channels soon become overloaded, then the dust particles block the lymph channels and a series of "dust depots" are formed in the air spaces.

As this obstruction in the lymph nodes increases with continued inhalations of dust, the pulmonary surface is covered with lesions, *the lymphatic vessels* being surrounded by beadlike fibrous tissue. These formations coalesce to form a massive fibrosis. Necrosis and cavitation eventually develop as a result of the decreased blood supply following extensive fibrosis. Emphysema is a usual complication but other conditions may develop, such as abscess, spontaneous pneumothorax, pulmonary artery thrombosis, hemorrhage, adhesive pleurisy, and atelectasis, all conditions which follow in the wake of any extensive pulmonary fibrosis.

Whether the fibrosis is due to a chemical change *in the silica particle*, as Gardner and many others believe, or to an inflammation caused by the hardness and sharpness of the dust has not been proved.* Mayer and Rapaport point out, however, that, though the hardness of quartz dust causes inflammation, the comparable hardness of emery dust does not. The degree of fibrosis depends on the degree of silica-dust accumulation, but once nodulization begins it is progressive. A tuberculous process develops in a great many cases.

The pulmonary fibrosis of silicosis is not always nodular; it may be diffuse. Fibrosis following inhalation of silica dust in quarries, mines, and potteries, or any sandblasting industry, tends to be nodular in type, characteristic *whorled nodules being scattered* over the lungs. Diffuse fibrosis is found in anthracosilicosis, siderosilicosis, and other mixed silicoses resulting from coal or ore mining or in the diatomaceous earth industry. Dust granulomas occurring as the alveolar walls are thickened by infiltration *of lymphocytes, plasma cells, and giant cells* and formation of a fibrous reticulum are not uncommon.

Nodular fibrosis, contrary to general opinion, is less damaging than diffuse fibrosis even in the milder grades, since even the slight thickening of the alveolar septa over

* The fibrous response to crystalline dusts (silica, etc.) depends on their being piezoelectrically active. For discussion of this hypothesis see Silas M. Evans, M.D., and Robert L. Kascht, M.D., The Pathogenesis of Silicosis, The Penna. Med. Jr., Vol. 52, Number 14, November 1949.—EDITOR.

cinoma cardiovascular diseases scleroderma diffuse bronchiectasis adenomatosis and other pulmonary disorders Diagnosis depends on (1) known exposure to dust laden atmosphere over a long period, not necessarily recent (2) clinical symptoms and (3) x ray findings Tubercle bacilli must be present in the sputum before tuberculosis can be considered evident

*Treatment* —Treatment of silicosis is symptomatic only The worker should at once be removed from exposure to dust hazards But the disease will progress even after exposure to the causative dust has ceased The treatment of complicating diseases which should be prevented when possible is of immediate concern Mayer and Rappaport distinguish between therapy for tuberculosilicosis and therapy for silicosis with tuberculosis In the former the routine rest therapy employed in tuberculosis is not remedial nor is radical treatment feasible in the latter the treatment is that for active tuberculosis except that it must be more conservative

For impairment of pulmonary function in pneumoconiosis Motley recommends the simultaneous use of intermittent positive pressure breathing and nebulization of such bronchodilator drugs as vaponefrin and isuprel to promote bronchial drainage and relieve bronchospasm

The effectiveness of antibiotic therapy has not been demonstrated but when silicosis is accompanied by a purulent infection injections of penicillin and other antibiotics and aerosol inhalations are indicated Surgical drainage of pyogenic abscesses may be required The use of metallic aluminum has been employed chiefly as a preventive measure the aluminum presumably rendering silica particles nontoxic by forming an insoluble coating of gelatinous aluminum hydroxide around the particles to prevent their absorption

In the early phase of the disease attempts should be made through inhalation and injection of penicillin to prevent bronchial infections In the second or pulmonary phase ventilatory insufficiency is evident from the occurrence of dyspnea cyanosis on exertion emphysema tachycardia venous engorgement and cardiocirculatory embarrassment vaponephrin inhalation the administration of aminophyllin and penicillin and the wearing of an abdominal belt are advocated For the final or cardiac stage in which there is evidence of right ventricular failure and some orthopnea the use of digitalis mercuhydrin aminophyllin and periodic inhalations of oxygen are recommended When there is evidence of total heart failure use of positive pressure inhalation and phlebotomy may bring some relief

## ANTHRACOSIS

Anthracosis is a disease of coal miners and differs from silicosis in that the deposits in the lungs are pure carbon and the disability is caused by blockage of the air passages by these deposits Tuberculosis is uncommon in cases of anthracosis but anthracosis without silicosis is rare since the layers of coal lie between rocks containing much silica

## ASBESTOSIS

Asbestosis results from inhalation of asbestos and differs from silicosis in that the coarse nodular fibrosis common in silicosis does not develop there being a finer and more general distribution of fibrous tissue and therefore greater respiratory embarrassment Continuous dyspnea out of all proportion to the clinical and radiologic findings is a characteristic symptom Corns due to penetration of the skin by asbestos fibers may occur on the hands arms and legs and clumps of asbestos are found in the sputum The progress of the disease is slower than that of silicosis

## SIDEROSIS

Siderosis occurs among iron-ore workers metal-drillers and hemite miners Two types of siderosis are encountered the red and the black The first is due to iron oxide dust and occurs among employees in industries using iron pigments The lung tissues are hard and reddish with massive areas of fibrosis though almost no evidence of silicosis or tuberculosis The disease resembles anthracosis The black type of siderosis

indicating fibrous nodules with a tendency to coalesce may be observed, the outer and lower lung fields characteristically showing fewer nodules Generally, the presence of these shadows without an attendant dullness to percussion indicates a silicosis, if the shadows are present together with rales and dullness to percussion tuberculosis is indicated In the late stages of silicosis nodulation becomes more consolidated throughout the upper and midlung fields, liver may become enlarged and the tips of the fingers become clubbed Emphysema becomes increasingly evident, at first it is functional and compensatory but at last becomes structural Emphysema arises as the accumulations of dust particles cause fibrosis and loss of breathing area and force the reserve breathing surface to function With spreading of the fibrosis, this reserve breathing service is lost, and the emphysema is no longer compensatory

Fig 158 —Silico-tuberculosis

usually with associated emphysema Dyspnea and cough are now prominent and on exertion, there is cyanosis due to cardiac insufficiency due, in turn to interference with capillary circulation

The victim of the disease may work for years without evident distress or disability except for the increasing breathlessness With development of tuberculosis fever sweating hemoptysis decreased strength and loss of weight become evident The veins of the neck show engorgement the

When nonspecific infection is superimposed suppuration is also present in addition to fibrosis and emphysema In advanced cases of silicosis with suppuration symptoms of right heart failure become evident and indicate cor pulmonale If the patient does not die of tuberculosis he dies of pneumonia combined with pulmonary heart disease

Differential diagnosis is difficult since pneumoconiosis simulates so many other diseases as tuberculosis sarcoidosis car

cinoma cardiovascular diseases scleroderma diffuse bronchiectasis adenomatosis and other pulmonary disorders Diagnosis depends on (1) known exposure to dust laden atmosphere over a long period not necessarily recent (2) clinical symptoms and (3) x ray findings Tubercle bacilli must be present in the sputum before tuberculosis can be considered evident

*Treatment* —Treatment of silicosis is symptomatic only The worker should at once be removed from exposure to dust hazards But the disease will progress even after exposure to the causative dust has ceased The treatment of complicating diseases which should be prevented when possible is of immediate concern Mayer and Rappaport distinguish between therapy for tuberculosilicosis and therapy for silicosis with tuberculosis In the former the routine rest therapy employed in tuberculosis is not remedial nor is radical treatment feasible in the latter the treatment is that for active tuberculosis except that it must be more conservative

For impairment of pulmonary function in pneumoconiosis Motley recommends the simultaneous use of intermittent positive pressure breathing and nebulization of such bronchodilator drugs as vaponefrin and isuprel to promote bronchial drainage and relieve bronchospasm

The effectiveness of antibiotic therapy has not been demonstrated but when silicosis is accompanied by a purulent infection injections of penicillin and other antibiotics and aerosol inhalations are indicated Surgical drainage of pyogenic abscesses may be required The use of metallic aluminum has been employed chiefly as a preventive measure the aluminum presumably rendering silica particles nontoxic by forming an insoluble coating of gelantinous aluminum hydroxide around the particles to prevent their absorption

In the early phase of the disease attempts should be made through inhalation and injection of penicillin to prevent bronchial infections In the second or pulmonary phase ventilatory insufficiency is evident from the occurrence of dyspnea cyanosis on exertion emphysema tachycardia venous engorgement and cardiocirculatory embarrassment vaponephrin inhalation the administration of aminophyllin and penicillin and the wearing of an abdominal belt are advocated For the final or cardiac stage in which there is evidence of right ventricular failure and some orthopnea the use of digitalis mercuhydrin aminophyllin and periodic inhalations of oxygen are recommended When there is evidence of total heart failure use of positive pressure inhalation and phlebotomy may bring some relief

## ANTHRACOSIS

Anthracosis is a disease of coal miners and differs from silicosis in that the deposits in the lungs are pure carbon and the disability is caused by blockage of the air passages by these deposits Tuberculosis is uncommon in cases of anthracosis but anthracosis without silicosis is rare since the layers of coal lie between rocks containing much silica

## ASBESTOSIS

Asbestosis results from inhalation of asbestos and differs from silicosis in that the coarse nodular fibrosis common in silicosis does not develop there being a finer and more general distribution of fibrous tissue and therefore greater respiratory embarrassment Continuous dyspnea out of all proportion to the clinical and radiologic findings is a characteristic symptom Corns due to penetration of the skin by asbestos fibers may occur on the hands arms and legs and clumps of asbestos are found in the sputum The progress of the disease is slower than that of silicosis

## SIDEROSIS

Siderosis occurs among iron ore workers metal-drillers and hemite miners Two types of siderosis are encountered the red and the black The first is due to iron oxide dust and occurs among employees in industries using iron pigments The lung tissues are hard and reddish with massive areas of fibrosis though almost no evidence of silicosis or tuberculosis The disease resembles anthracosis The black type of siderosis

occurs among iron-workers and metal-grinders and polishers, and, since silica is usually present in the victims working atmosphere, silicosis and tuberculosis co-exist with the disease

## OTHER INORGANIC DUST DISEASES

New inorganic dust diseases are constantly being reported, diseases such as occur among workers in bauxite beryllium granite vanadium, *etc* The symptoms of these diseases differ little from those of silicosis

It has been shown that prolonged inhalation of chromate dust produces carcinoma of the lung Exposure to radon in uranium mines produces also malignancy of the lungs ( Schneeberger Lungen Krankheit ) (H Brieger)

## ORGANIC-DUST DISEASES

Diseases arising from exposure to organic dusts are not true pneumoconioses but should be considered here because of the pulmonary involvement Some of these inhaled materials contain fungi and living bacteria Anthrax bacilli may be inhaled by workers in processing hair furs or skins Fungi may be inhaled by those threshing grain

## SHAVER S DISEASE

Shaver s disease, named for its discoverer occurs among workers exposed to fumes from the electric furnace used in the production of fused aluminum The particles of aluminum are extremely small from 0 02 microns to 0 5 microns in diameter This is probably the reason for the very rapid development of the disease which causes profound pulmonary damage If death comes it comes in a few months whereas the silicosis victim lingers for years

## THE PNEUMONIAS

Pneumonias due to bacterial and rickettsial agents have been discussed in Chapters 2 and 5 Only pneumonias due to the aspiration of certain materials or to miscellaneous causes are described here

### Aspiration Pneumonias

*Lipoid pneumonia* results from the aspiration of fatty substances such as mineral oil cod liver oil oily nose drops and milk Forced feeding of cod liver oil castor oil or mineral oil to crying children is no infrequent cause Although lipoid pneumonia occurs more often in children adults who commonly use nose drops may develop it Motor mechanics occasionally inhale fuel oil and machine workers oil from broken pressure lines both may develop lipoid pneumonia Vegetable oils are less irritating than animal oils the latter having a high fat content and being easily hydrolyzed Mineral oil is also less irritating than animal oils but may act as a foreign body and produce inflammatory changes

Roentgenologically the infantile type of lipoid pneumonia simulates atypical pneumonia In the adult the clinical symptoms in the later stages of the disease seem to indicate a chronic pneumonitis On $x$ ray the findings at first resemble those of the hepatization stage of lobar pneumonia then with the development of a dense fibrosis,

they may mimic those of a bronchogenic carcinoma Suspicion of a neoplasm may sometimes lead to a pneumonectomy where a lobectomy would have sufficed

### Miscellaneous Pneumonias

*Post irradiation pneumonia* is an infrequent sequel to irradiation therapy for breast cancer In the presence of such a cancer it may be difficult to decide whether the fibrosis present is due to the neoplasm or to the effect of the irradiation

Roentgenograms may reveal consolidation extending from the hilum into the lung fields and occasionally a pleural effusion These irradiation lesions may disappear spontaneously without leaving permanent damage The symptoms of post irradiation pneumonia—cough irregular periods of fever and dyspnea—simulate those of chronic pneumonitis

### Chemical Pneumonitis

Exposure to a great number of irritating gases such as nitrous oxides sulphur oxides fluorides and others may produce chemical pneumonitis as was observed in the Donora episode (H Brieger)

## ALLERGIC PNEUMONIA LOEFFLER'S SYNDROME

Loeffler's syndrome is characterized by transitory migratory parenchymal infiltrations mild pulmonary symptoms a high blood eosinophilia and uneventful clinical course and spontaneous resolution Its etiology is uncertain It is frequently observed in asthmatic or allergic individuals A tuberculous origin seems unlikely since tuberculin tests may be either positive or negative Since parasites are not infrequently found in cases of this disease a parasitic origin for it has been given some credence The allergic theory of its origin however has received most support

## MYCOTIC DISEASES OF THE LUNG

The mycoses are discussed elsewhere in detail but because of the frequency with which pulmonary mycosis occurs points pertaining to mycotic lung involvement deserve special comment (*See* Chapter 9)

Actinomycosis —Primary pulmonary actinomycosis is usually bilateral and involves especially the lower lobes although no location is necessarily spared so that tuberculosis bronchogenic carcinoma or almost any other condition may be mimicked Early cases are characterized by a mild type of respiratory infection with low grade fever cough and varying amounts of mucoid sputum which later becomes thick purulent and sometimes blood streaked The initial lesions subsequently show abscess formation and extension to the pleura and thoracic cage together with the development of draining cutaneous fistulas Pleural involvement leads to thickening of the pleura pleuritic pain and occasionally effusion In untreated or unresponsive cases signs of a chronic debilitating disease eventually appear together with clinical and laboratory evidence of a severe infection Deformities of the chest wall may result

X rays of the chest usually reveal extensive patches of consolidation usually bilateral and involving the bases Fan shaped masses radiating from the hilum may be encountered More uncommon are apical

lesions resembling those of the active reinfection type of tuberculosis. The mediastinum becomes distorted in advanced cases, and pleural and rib involvement are frequently demonstrable.

The demonstration of typical "sulfur granules" or mycelial filaments in the sputum or in the pus from draining sinuses is generally diagnostic, but it should be remembered that pathogenic strains of *A. bovis* constitute a common contaminant of the gums and saliva of normal individuals. A biopsy of the wall of a draining sinus may show granules when none are present in the drainage.

NOCARDIOSIS.—Increasing attention is now being devoted to nocardiosis because of its strong clinical resemblance to tuberculosis. It is the general impression that the disease is much more frequent than its rate of diagnosis would indicate. The picture is primarily that of pulmonary involvement, with signs and symptoms that are, at first, mild and similar to those of bronchitis with unproductive cough, low grade fever, and vague chest pain. Even as the disease progresses, the patient does not appear as sick as the radiographic evidence would indicate. Empyema is a frequent complication, and fistulous tracts similar to those with actinomycosis are apt to occur in chronic cases. Hematogenous spreading accounts for involvement of other organs, especially those of the central nervous system; metastatic brain abscesses occur in about 25 per cent of cases. The lower lung fields again appear to be somewhat more often affected, but apical lesions are by no means uncommon. Certainly in any obscure lung disease suspected of being tuberculosis, nocardiosis should be considered when tubercle bacilli cannot be found. Of interest here is the fact that the method of concentrating sputum for acid fast studies actually destroys *N. asteroides*.

COCCIDIOIDOMYCOSIS (SAN JOAQUIN VALLEY FEVER).—Coccidioidomycosis follows inhalations of dust containing the spores of Coccidioides immitis and, in the vast majority of cases, is limited to an acute infection of the upper respiratory tract. This infection is benign and generally mild or even subclinical, occasionally it is severe. By skin testing with coccidioidin, it has been shown that, in the endemic areas, most of the inhabitants have been previously infected with the primary pulmonary type of coccidioidomycosis. Chest pain accompanies most cases, usually, it is substernal and aggravated by respiration or cough. Cough, chills, and fever, headache, sore throat, and general malaise are other frequent complaints. Some stress the occurrence of substernal pain on swallowing as a peculiar but highly suggestive feature in about 25 per cent of the cases. Allergic skin manifestations, such as erythema nodosum or erythema multiforme accompany about 5 or 10 per cent of the cases. Hemoptysis is very infrequent at this stage. Physical findings are variable. On x ray examination the majority of cases exhibit a fairly well-defined homogeneous density radiating peripherally in fan shaped fashion from the hilum. Discrete nodular lesions in the periphery are less common but are typical of the disease and probably represent an unresolved infiltration of the former type. Peribronchial infiltration and hilar and mediastinal adenopathy are frequent associated *findings and may constitute the only evi*dence of the disease. The lower lung fields are much more frequently involved, but in some cases apical reinfection tuberculosis may be closely simulated. Complete recovery can be anticipated in from 6 to 8 weeks, *but, in a small percentage of cases* characteristic thin walled cavities may persist. These are usually apical (70 per cent) and may close spontaneously (if small) or cause no subjective complaint. In a few cases, however, recurring hemoptysis with persistent or giant cavitation eventually necessitates pneumothorax, phrenic crush or even lobectomy for cure. Before any such decision, refractoriness to a therapeutic trial of bed rest should be demonstrated, most authorities feeling that the therapy for primary pulmonary coccidioidomycosis is in this respect essentially the same as the therapy for tuberculosis. On the other hand one should recall that the sputum of those with coccidioidomycosis is never infectious, for it contains only endospores which are not infective.

In about 1 case in 100 the primary form goes into progressive coccidioidomycosis then the course becomes chronic the disease systemic and the prognosis extremely dark Respiratory symptoms and fever persist and are joined by generalized weakness and wasting as well as by symptoms from bone joint cerebral and visceral spread Negroes Mexicans and Filipinos appear to be particularly susceptible The mortality rate for the progressive type of the disease is over 50 per cent

HISTOPLASMOSIS (DARLING'S DISEASE) — Men are affected twice as often as women Recent skin testing surveys with antigen derived from cultures of *H capsulatum* have revealed a startling degree of past infection among inhabitants of endemic areas It is felt that there is a benign type of histoplasmosis similar to that of coccidioidomycosis a type characterized by a subclinical or mild clinical course from which recovery is complete Sensitivity to histoplasmin and the presence of small pulmonary calcifications indistinguishable from healed tuberculous lesions are the only residua of the disease There are astonishingly few instances of the progressive systemic form of the disease Symptoms include dry cough weakness dyspnea chills and fever night sweats chest pain and occasionally hemoptysis Weight loss is often marked Chest x rays may show anything from increased bronchovascular markings to areas of pneumonitis The classical mycotic picture of fan like hilar radiations occurs in only a third of the cases Miliary studding of both lung fields occurs in snowstorm fashion despite the negligible incidence of apical involvement

In the overall picture the lung findings play a very small part in comparison to the hepatomegaly splenomegaly lymphadenopathy and marked inanition which accompany visceral histoplasmosis Leukopenia and anemia occur as a result of bone marrow destruction The progressive form of the disease is almost universally fatal

NORTH AMERICAN BLASTOMYCOSIS (GILCHRIST'S DISEASE) — Though a great many primary benign forms of coccidioidomycosis and histoplasmosis have been demonstrated in recent years no such corresponding variety of forms has been discovered for blastomycosis Nearly all systemic cases are fatal progressing from a mild respiratory infection to extensive lung involvement In the early stages a dry nonproductive cough chest pain and low fever occur purulent blood streaked sputum dyspnea and high fever come later General debility ensues and night sweats may become particularly severe In most instances there is concomitant skin involvement Subcutaneous abscess formation with subsequent cutaneous fistulas is rather typical

MONILIASIS — Bronchopulmonary moniliasis is not uncommon but in many instances is never diagnosed as such The signs and symptoms are those of chronic bronchitis— chiefly a persistent cough productive of gray flecked mucoid sputum containing budding yeastlike cells The course is mild and chronic and roentgenograms reveal little more than a slight peribronchial infiltration

ASPERGILLOSIS — Pulmonary involvement in aspergillosis is uncommon but when it occurs often shows a marked similarity to that in tuberculosis

CRYPTOCOCCOSIS (TORULOSIS) — The *Cryptococcus neoformans* has a predilection for the central nervous system and to some degree the lungs In fact the organism is thought to gain entrance via the respiratory tract where it causes a mild infection characterized by persistent cough and low fever Any portion of the lung may be involved

GEOTRICHOSIS — There are a number of types of *Geotrichum* which cause geotrichosis and all are frequent contaminants The most frequent form of the disease is bronchopulmonary but in most instances the only symptom is a persistent and harrassing cough productive of a small amount of mucoid sputum

A pulmonary form of the disease also exists but is much less common It is characterized by a systemic reaction with fever leucocytosis purulent sputum and occasional hemoptysis a picture not unlike that of tuberculosis

SPOROTRICHOSIS — Pulmonary forms of this disease rarely occur for it involves primarily the lymphatic system and other systems of the body When it does occur it presents the picture of a low grade pulmonary infection

## DISEASES OF THE PLEURA

Pleurisy, or pleuritis, is a commonly occurring inflammation of the pleura and may be primary or secondary acute or chronic A primary pleuritis which occurs but rarely is blood borne from a distant focus of infection A pleural inflammation may affect only a circumscribed portion of the serous membrane or involve the entire surface of the pleura According to the characteristics of the inflammatory exudate the pleurisy is designated *fibrinous* or plastic (dry), *serofibrinous* (wet) or *purulent* (empyemic) These three types of pleurisy really represent different stages of the same pathologic process and sometimes cannot be clearly differentiated from one another

*Fibrinous Pleurisy —Etiology* —Pleural inflammation usually results from infection by direct or lymphatic extension most often from the lungs but may extend from other thoracic structures such as the pericardium vertebra or any organ beneath the diaphragm The common etiologic agents are tubercle bacilli streptococci pneumococci staphylococci and viral and other pathogenic agents Inflammation of the pleura may occur in such conditions as rheumatic fever brucellosis tularemia fungous infections disseminated lupus erythematosis Pick s disease diabetic coma dehydration and uremic states trauma pulmonary infarction irradiation pneumonitis and neoplastic diseases Also the terminal stage of various chronic and debilitating diseases may be attended by an associated pleurisy

*Pathology* —The fibrin may be absorbed and the appearance of the pleura remain unchanged or the pleural membrane may permanently lose its glistening appearance and become thickened by the inflammatory

exudate which deposits fibrin on the pleural surfaces and brings about the formation of firm fibrinous adhesions that glue the two pleural surfaces together The process may stop at this stage or progress to the secondary stage in which a copious exudation of serum takes place

*Symptoms and Signs* —The first clinical manifestation of the disease may be a sudden sharp pain a pain increased by bending toward the uninvolved side and diminished by supporting the affected side The pain may be aggravated by breathing or may be present only on deep breathing or coughing The patient may be seen lying on the affected side and attempting to restrain movements of the chest to lessen the pain and distressing cough This tends to increase respiratory embarrassment and may increase dyspnea arising from pulmonary compression and decrease of vital capacity

The physical signs depend to a large extent upon the amount of fibrinous exudation In some patients there may be little or no characteristic signs except a to-and-fro friction rub heard over the lower lateral portions of the chest This is a characteristic sign but is absent in some cases On the other hand there may be restricted movements of the chest on the affected side abdominal breathing occasionally a weak unproductive cough chills and fever The diaphragm may be elevated in cases of a pronounced fibrinous exudation and the percussion note may be dull There is local tenderness which may be aggravated by the pressure of the stethoscope Breath sounds are diminished on the affected side and intensified on the uninvolved side Roentgenographic examination may show nothing abnormal in the early stages of the disease but after the pleura has become thickened a band of uniform density with a sharply defined inner margin may be noted between the lungs and ribs When there is an underlying pulmonary process the evidence of pleurisy is obscured unless tuberculosis is present in which case *x* ray findings of tuberculous lesions at the apex may cause pleurisy to be suspected

*Diaphragmatic Pleurisy* —Pleurisy may develop in the serous lining of the upper surface of the diaphragm without involvement of any other part of the pleura It is usually fibrinous in nature but may occasionally be serous or even purulent The resulting pain will not be located over the inflamed area but referred to the shoulder or to the abdominal region according to the part of the diaphragm affected The central segment of the diaphragm receives its nerve supply from the phrenic nerve infection in that area will produce a referred pain in the supraclavicular region of the shoulder The peripheral rim of the diaphragm is supplied by the lower six intercostal nerves, inflammation in that region causes referred pain in the abdomen The pain which is generally increased on deep breathing or coughing may be mild or if the pleurisy is acute recurrent sharp pains may occur attended by eructation of gas and vomiting Cough is frequently present and dyspnea pronounced The abdomen may be rigid and boardlike but usually is not sore on pressure Percussion sounds are usually negative but friction rub is occasionally heard in the diaphragmatic region

Adhesions are found between the diaphragmatic surface of the pleura and the diaphragm either at its periphery or at the costophrenic or mediastino-phrenic angle or may arise from the mediastinal surface of the lung connecting that surface of the pleura with the diaphragm or with the pericardium Differential diagnosis may be confusing In some cases perforating peptic ulcer appendicitis or gall bladder disease has been diagnosed and this has led to abdominal operation Radiologic examination however may reveal a shadow in the dependent portion of the thorax and flattening and immobility of the diaphragm Tenderness on deep pressure should suggest abdominal disease its absence is suggestive of diaphragmatic pleurisy The white blood-cell count is elevated in all these diseases

*Treatment* is the same as in other types of pleurisy —use of a binder on the abdomen to splint the affected area and application of an ice pack to relieve pain

*Serofibrinous Pleurisy* —Serofibrinous (wet) pleurisy frequently follows fibrinous pleurisy although the dry stage may not have been recognized The wet stage is due to exudation of thin serous fluid into the

pleural cavity. The physical signs will depend on the amount of effusion present and the mobility of the mediastinum. Usually there is an impairment of respiratory movement on the affected side and obliteration of the intercostal depressions over the site of the fluid. Respiratory fremitus is absent and the percussion note is usually flat over the fluid but may be tympanitic or Skodiac above that level. The line of dullness on percussion may assume an Ellis S-curve, with the highest curve in the axilla changing position with posture. The heart, trachea, and mediastinal contents may be displaced contralaterally. With effusion on the right side the liver dullness may be depressed below the costal margin.

Laboratory examination of the fluid will show that it has a specific gravity of 1.018 or more and a high albumin content; the presence of leukocytes will also be noted. Blood, chyle, or cholesterol crystals may be present and suggest the character of the primary lesion. Bacteriologic study will reveal the nature of the inflammatory agent. Fungi are only rarely found in the pleural exudate. A search should be made for tuberculosis if a large percentage of lymphocytes are present. A bloody exudate should suggest malignancy.

Roentgenologic studies before development of fluid or thickening of the pleura takes place may yield few findings beyond restriction of diaphragmatic movements on the involved side. To be visible from 300 to 400 cc. of fluid must usually be present, although a lateral *x* ray, with the patient prone, may reveal a smaller quantity.

Whereas a simple pleuritis may be of short duration, a serofibrinous pleurisy *heals slowly*. *As the effusion gradually* diminishes fibrous adhesions, as part of the healing process, obliterate part of the pleural space. If the exudation becomes purulent, however, the exudate is not absorbed and an empyema develops so that healing cannot take place until the pus is removed. Occasionally a bronchopleural fistula develops allowing the pus to escape through the bronchus.

A serofibrinous pleurisy may heal within a few weeks or may last for months, depending on its severity and on the treatment used. In from 70 to 80 per cent of the cases the pleurisy is of tuberculous origin and unless this is recognized and treated, manifest pulmonary tuberculosis will be noted in from 40 to 50 per cent of the cases within 5 or 6 years. On the other hand, if patients with tuberculous pleurisy are hospitalized for a period of 6 months, pulmonary tuberculosis *will develop in approximately only* 10 per cent of the cases.

Tubercle bacilli frequently invade the pleura usually within 3 to 6 months of a primary infection or during post-primary hematogenous dissemination and produce a tuberculous pleurisy. Tubercle bacilli may appear first in the pleura, the development of pulmonary tuberculosis being secondary. *In these cases, whether fibrinous or serofibrinous*, scar tissue may develop to bind the pleural surfaces together, thus promoting healing. When tuberculosis of the lung is known to be present, diagnosis of a pleurisy is not difficult, but when the presence of tuberculosis is not recognized diagnosis may be difficult. If the pleurisy is of the dry type the only evidence of tuberculous infection may be a low grade fever, and the diagnosis is usually not made until evidence of the tuberculosis is produced.

*Diagnosis.* — The clinical diagnosis of serofibrinous pleurisy can usually be made on a basis of (1) a history of increasing dyspnea following thoracic pain or discomfort, (2) careful physical examination, thoracentesis, and laboratory tests, and (3) confirmation by means of fluoroscopic and radiographic examinations. Small pleural effusions are elusive on examination and are often overlooked. X ray studies are therefore necessary for the detection of small, encapsulated, or atypically located effusions.

Aspirated fluid provides the only absolute evidence of a pleural effusion.

The laboratory examination of the fluid may show a normal leucocyte count or a slight lymphocytosis. *Examination of a* tuberculous effusion shows a characteristic straw-colored, thin or cloudy fluid having a specific gravity of 1.018 or more and a high albumin content. The fluid may contain a number of red blood cells and 70 per cent or more lymphocytes. Bacteriologic study should always be made. Culture of the fluid

may be negative even when the presence of tuberculosis is known and repeated cultures may be required In doubtful cases recourse may be had to the tuberculin test A fungous infection is seldom found When the percentage of lymphocytes is high a test for tuberculosis should invariably be made preferably by guinea pig inoculation If the exudate is bloody malignancy should be considered

There are two diagnostic problems therefore in suspected serofibrinous pleurisy (1) differentiation between this type of pleurisy and conditions producing similar appearances (thickened pleura pneumonia new growths the empyemas hydrothorax atelectasis pericarditis with effusion and subdiaphragmatic conditions such as echinococcus of the liver abscess of the liver and subphrenic abscess) and (2) identification of the causative microörganism

*Treatment* — The treatment of pleurisy is directed to relief of pain and pressure symptoms Bed rest is fundamental in order to treat the underlying disease successfully In dry pleurisy bed rest alone may bring recovery Salicylates barbiturates codein heat adhesive strapping and counter irritants have all been recommended for dry pleurisy When the pain is severe injection of procaine solutions into the skin above the affected area or into the pleura brings relief Diffuse pain is sometimes treated with intercostal nerve block by injection of a 1 per cent procaine solution Resolution or organization of the initiating disease brings about subsidence of symptoms

When the amount of fluid is profuse aspiration may be necessary to relieve the dyspnea and pressure symptoms but aspiration should be delayed until the very acute febrile stage has passed unless the dyspnea becomes severe When aspiration is done early in the course of the disease the fluid re accumulates rapidly If allowed to remain unaspirated for a number of weeks pleural thickening may develop with permanent damage to respiratory function On the other hand if tuberculosis is present fluid removal may allow too rapid re-expansion of the lung and make the condition worse Only enough fluid should be aspirated to relieve the dyspnea as the remainder tends to be absorbed spontaneously if not aspiration should be repeated The fluid should be aspirated as much as possible before signs of cardio-respiratory distress develop If the patient complains of a pulling sensation in the chest is dyspneic or is coughing slightly thoracentesis must be stopped at once for these symptoms are an indication of too rapid re-expansion of the collapsed lung or of a shifting mediastinum and show that therefore a torsion of the great vessels at the base of the heart is threatened A small amount of air introduced will bring symptomatic relief and permit satisfactory radiologic and fluoroscopic determination of the site of the fluid Replacement of fluid by air is contraindicated in nontuberculous pleurisy and care should be taken by means of a check valve apparatus to prevent the entrance of air Before withdrawing the aspirating needle from 50 000 to 100 000 units of penicillin in 50 cc of saline solution may be introduced into the pleural cavity through the same needle in order to prevent infection But if the bacteriologic examination has revealed penicillin resistant organisms streptomycin (not to exceed 10 000 units per cc ) may be substituted If the effusion is tuberculous use of streptomycin is not recommended

A pneumothorax may be performed at the time of thoracentesis only if there is radiologic proof of the presence of pulmonary tuberculosis If a pneumothorax is done it should be performed before adhesions form otherwise an empyema may follow

*Pleural calcification* is rather uncommon and results from a tuberculous pleurisy or empyema pleural hematoma or hemothorax Physical signs of thickening of the pleura may indicate a fibrosis rather than a calcification When associated with an active tuberculous empyema calcification becomes serious for it acts as a foreign body and prevents healing and also by causing rigidity of the pleura prevents collapse of the cavity by thoracoplasty Diagnosis is made radiologically No treatment is given unless complications demand radical removal of the calcified parts of the pleura and complete thoracoplasty

## Empyema

*Etiology.*—Empyema, or pus in the pleural cavity, seldom if ever, occurs as a primary disease. Usually, it is secondary to an intrapulmonary infection, such as pneumonia, bronchiectasis, pulmonary abscess, pulmonary mycosis, or tuberculosis, or to a mediastinal or pericardial infection. Occasionally it results from stab wounds of the chest or rupture into the pleural cavity of mediastinal or subphrenic abscesses. The bacterial organisms most frequently found in empyema are pneumococci, streptococci, staphylococci, and tubercle bacilli.

The empyema usually forms over the site where the pneumonic process encounters the pleura and, in recumbent patients, tends to form in the posterior part of the chest. Undiagnosed and untreated, the empyema may burrow through the lung to a bronchus, or it may form "nests" in the parenchyma.

*Clinical Features.*—The symptoms of empyema are usually clouded by those of the primary disease but are increased by the inflammatory effect of the fluid formation on the parenchyma. In an extensive empyema the usual signs of pleural effusion are produced—dullness to percussion and immobility on one side of the chest, displacement of the heart away from the affected side, diminution of breath sounds and vocal fremitus over the affected area with tubular breathing above. These signs will be absent in small empyemas and the diagnosis delayed. Nevertheless, even if the quantity of fluid is small, limitation of respiratory motion may be noted.

X-ray studies may be helpful in the diagnosis but diagnosis cannot rest upon these findings alone, since similar shadows are caused by various collections of fluid in the lung. Aspiration will produce a thin, grayish fluid in early cases; later this becomes a thick, creamy pus which microscopically shows a high polymorphonuclear cell count. Laboratory studies will reveal the types of bacteria present. As the disease progresses the pus becomes very foul, indicating a mixed infection and the probable presence of a bronchopleural fistula.

Large accumulations of pus may erupt spontaneously through the chest wall (empyema necessitatis). A chronic empyema may develop from an acute empyema if the latter is untreated. In some instances, the patient may continue to work without discomfort with a large mass of pus in the chest. Eventually a gradual loss of weight, cough, and pain in the chest may cause him to seek a physician, and a suspicion of tuberculosis may be aroused.

Empyema may be distinguished from a serofibrinous pleurisy by its history of a preceding pneumonia and the bacteriologic findings. It is differentiated from pneumonia by the great toxicity present in empyema. Differentiation from pulmonary abscess is made on the patient's history, for the abscess usually follows an operation or aspiration of a foreign body; also, the abscess is rarely so extensive as an empyema becomes. Laboratory studies of the fluid, together with the patient's history, will distinguish between a tuberculous and a nontuberculous empyema.

*Treatment.*—Treatment of empyema is based on adequate drainage of the infected pleural cavity, elimination of organisms, obliteration of the empyema cavity, and reexpansion of the lung. Since the advent of the antibiotics, the treatment of empyema may be medical only, and early therapy may now be expected to bring recovery. Surgical intervention can be delayed with safety for one or two weeks, until it can be determined whether antibiotic treatment with aspirations will be successful.

A complete aspiration of the fluid daily and cleansing of the cavity with from 50 to 100 cc. of isotonic saline solution containing 1000 units of penicillin per cc. is advised. Even if operative drainage seems inevitable, preoperative antibiotic instillations may help to bring about localization of the empyema and prevent massive collapse of the lung. Empyema due to Gram-positive organisms requires treatment with penicillin, whereas those due to Gram-negative organisms or tubercle bacilli require streptomycin or other antibiotics. They should be given systemically and by instillation into the pleural cavity. They may be administered singly or together. Supportive treatment to maintain a satisfactory nutritional state is

important in either medical or surgical therapy

Improvement may be striking within 48 hours Aspiration of fluid and irrigation must be done daily When the exudate becomes sterile intrapleural antibiotic therapy can be discontinued and aspiration performed only when the fluid has not been reabsorbed Parenteral administration of the antibiotic should be continued until the temperature has been normal for a period of 3 days or more The aspiration of fluid must be complete each time it is attempted Daily x ray and fluoroscopic studies are advised during this period

Antibiotic therapy may suffice in empyema necessitatis Chronic empyema particularly when due to anaerobic bacteria will usually require operative drainage or pleural decortication

Recently the catalytic and enzymatic properties of streptokinase and streptodornase in promoting hydrolysis of fibrin and pus have been recognized Lysis of the pus in empyema following injection of these agents permits removal of the exudate by thoracentesis or by closed drainage through a thoracotomy tube They prevent further bacterial infection and promote closure of the cavity and healing

## Pneumothorax

*Etiology* —Pneumothorax is an accumulation of air or gas in the pleural cavity It follows a wound in the chest spontaneous rupture of the visceral pleura caused by underlying disease or artificial induction for diagnostic or therapeutic purposes Spontaneous pneumothorax once considered almost always due to a pulmonary tuberculosis is usually caused by rupture of emphysematous blebs asthma or rupture of a lung abscess It may be secondary to mediastinal emphysema (*see* page 957)

Spontaneous pneumothorax is of several types the closed type with small variations in intrapleural pressure causing mild symptoms the open type with atmospheric pressures due to communication with the bronchial tree causing moderately severe symptoms the tension or valvular type permitting inspiratory ingress of air and causing alarming symptoms due to highly positive intrapleural pressure Spontaneous pneumothorax of unknown etiology may occur in an apparently healthy individual It is usually observed in persons between the ages of 20 and 40 and more frequently in men than in women It is sometimes reported in the newborn and very young infants

*Pathogenesis* —The immediate cause of a spontaneous pneumothorax may be some act of the patient—heavy lifting sudden twisting of the body severe coughing or straining at stool Often the patient cannot recall any precipitating act He may have been lying in bed

When rupture of the pulmonary tissue takes place air escapes into the pleural cavity If the lung becomes completely collapsed there will be a shift of the heart and mediastinum toward the opposite side The edges of the tear may become sealed by the fibrinous effusion which follows no further air escapes and the lung gradually re-expands If the edges of the tear are held apart by adhesions on one side and by the collapsing lung on the other the gap may remain open The collapsed lung may become atelectatic in time the lung becomes permanently unable to re-expand When the opening becomes valve like so that there is an increasing escape of air into the pleura without release in the opposite direction a tension pneumothorax develops

Pneumothorax may be recurrent Coughing may cause a new separation of the healed edges of the hole and allow air to escape again into the pleural cavity With each coughing spell more and more air will be trapped and the mediastinum and heart further displaced In some instances the excessive tension may cause downward displacement of the diaphragm and if high enough may ultimately bring about a herniation of the pleural space rupturing into the mediastinum or even into the opposite pleural cavity Bilateral pneumothorax may occur if complete death will ensue Sometimes the pneumothorax will alternate from side to side

Little or no effusion occurs in simple benign pneumothorax However if there is underlying tuberculosis and the pleura becomes infected with tuberculous exudates a

clear serous effusion forms causing a hydropneumothorax; if there is pus, a pyopneumothorax results. The former is more common in the course of tuberculosis and the latter in suppurative conditions, such as lung abscess.

*Clinical Features.*—The symptoms of pneumothorax vary according to whether the onset is sudden or insidious, the amount of air that has accumulated in the pleural space and the general condition of both the affected and unaffected lungs. The pneumothorax may produce few symptoms until the accumulated air causes an alarming climax. The patient who has been unaware of more than a vague discomfort in his chest may, upon exertion, become dyspneic and, for the first time, consult a physician. In sudden onset, a sharp pain in the chest, upper abdomen or back, tightness in the chest, acute dyspnea, marked cardiac palpitation and a feeling of suffocation may follow a sensation of something's having snapped in the chest. These symptoms may subside if the escape of air into the pleural cavity ceases and compensation takes place by depression of the diaphragm and shifting of the mediastinum and heart toward the other side. If the tension should increase, preventing return of blood to the heart, the patient becomes cyanotic and may die of asphyxia and cardiac failure.

The physical signs also vary according to whether the pneumothorax is complete or partial, the condition of the affected lung and the fixity of the mediastinum. In partial pneumothorax diminished expansion is noted on the affected side. The percussion note is hyperresonant and voice sounds are diminished or absent on the affected side. Breath sounds are absent or diminished on that side and exaggerated on the opposite side if the healthy lung is over-expanding in compensation. In complete pneumothorax the signs are more striking with immobility of the chest and absence of both breath and vocal sounds, and a tinkling coin sound may be heard. A pericardial knock may be noted in a left sided penumothorax without fluid. Shaking the body when fluid is present produces a pathognomonic succussion splash. The larger the hole, the deeper are the amphoric breath sounds.

If a tension pneumothorax develops, a widening of the intercostal space on the affected side can be observed with obliteration of the intercostal depressions. The chest on that side becomes immobile and the chest wall appears smooth and bulging, the trachea and the apex of the heart are usually displaced toward the other side. The percussion note becomes hyperresonant or tympanitic. Voice and breath sounds are not heard. Occasionally, as the tension gradually increases, the diaphragm is lowered and liver dullness is depressed. Tachycardia and arrhythmias may give evidence of marked displacement of the heart and mediastinum.

Roentgenologic examination is necessary to determine the degree of collapse of the lung.

*Diagnosis.*—If the pneumothorax is only partial, the slight attending pain may be overlooked or be regarded as pleurisy. When more complete, the severe pain accompanied by dyspnea may be mistaken for perforation of a peptic ulcer or cardiac infarction. Large pulmonary cavities and diaphragmatic hernias or a congenital cyst may simulate a pneumothorax and differentiation may be difficult.

*Treatment.*—Therapy is largely symptomatic in patients with an open or closed spontaneous pneumothorax uncomplicated by an underlying infection. Quiet bed rest, sedatives for relief of pain and careful watching for development of a valvular mechanism in the tear are necessary, with reassurance of the frightened patient. Frequent roentgenographic and fluoroscopic examinations should be made to determine progress of the disease. Control of cough will help to prevent further forcing of air into the pleural cavity. The tear should be given a chance to heal without interference. The air may be absorbed and the lung become expanded within 3 to 6 weeks. An intrapleural pressure which becomes increasingly negative calls for closing the pleural cavity. Intrapleural measurements therefore are of diagnostic aid.

In cases of recurrent spontaneous pneumothorax, attempts have been made to obliterate the pleural space by creation of an aseptic or sterile pleuritis by application of

irritants to the surface of the lung. The resulting inflammatory reaction causes thickening of the visceral pleura and prevents further rupture of the peripheral blebs. The materials used are the patient's own blood, 50 per cent glucose solution, 1 per cent nitrate of silver, gomenol in mineral oil or lipiodol or talc with or without sulfonamide. Good results have been obtained in numerous cases. Pleural leaks may be successfully closed (by suture of the involved area), emphysematous blebs excised, emphysematous cysts invaginated and ruptured bronchogenic cysts treated by excision or lobectomy. Recurrences following treatment have not been reported.

In cases of pneumothorax in which the pressure is positive and the patient is distressed by the high tension, clinical relief may be obtained by removal of the air through thoracic puncture by use of an indwelling wide-bored aspirating needle or a trocar and cannula inserted into the pleural cavity through the fifth intercostal space and attached to a water trap or constant suction apparatus. Aspiration of fluid may be required in cases of hydrothorax.

When the collapsed lung fails to re-expand because of fibrous adhesions, injections of streptokinase and streptodornase may be successful in producing hydrolysis of the fibrin. When the liquified material is repeatedly aspirated, the lung may re-expand, thereby eliminating the need for decortication.

*Prognosis*.—Prognosis is good in simple benign pneumothorax when the tear becomes sealed and the lung re-expands following absorption of the air. If a complication is present, such as tuberculosis, empyema, bronchiectasis or acute inflammation, the condition is serious. Tension pneumothorax impedes the circulation and is therefore dangerous. A chronic pneumothorax may develop if the air is not absorbed and the lungs fail to expand, but if fibrosis finally occurs the hole may be sealed and then the lung gradually expands. Development of a pyopneumothorax indicates the presence of an underlying tuberculosis or some other serious infectious process.

## Hydrothorax

Noninflammatory serous fluid may collect in one or both pleural cavities secondary to a constitutional disease, such as chronic heart disease or chronic nephritis, and cause a hydrothorax. Other causes may be cirrhosis of the liver, nutritional hypoproteinemia, lung or mediastinal tumor, Meigs syndrome, or pressure on the pulmonary veins. The fluid oozes slowly from the pleural tissues and accumulates. The pleural surfaces remain normal in appearance or slightly cloudy and swollen if the hydrothorax is long-standing.

The symptoms are those of pleural effusion and usually occur only when there is encroachment upon the heart and lungs. An associated edema of the lung will cause cough with expectoration. The transudates occur more often on the right than on the left side and, when bilateral, are more profuse on the right side. The roentgenologic findings are the same as those in serofibrinous pleurisy. A diagnostic thoracentesis will reveal the noninflammatory nature of the transudate, which is a clear, pale straw-colored fluid of low specific gravity (below 1.018), comparatively low cell count and a protein content of less than 5 per cent. It does *not* clot upon standing. The fluid may be aspirated but will recur unless the primary or initiating cause is removed.

## Hemothorax

*Etiology*.—Hemothorax is a collection of blood within the pleural cavity, resulting either from trauma or from an internal hemorrhage of an intercostal, mammary or pulmonary vessel. The trauma may result from a blow, from a stabbing, from a crushing of the chest, or from a gunshot wound. A fractured rib may lacerate the lung. Other occasional causes are pulmonary infarction, pneumococcal pneumonia, rupture of a thoracic aneurysm, blood dyscrasias, tuberculosis and invading carcinoma. A hemothorax accompanying a traumatic pneumothorax may simulate an acute abdominal disease and lead occasionally to unnecessary surgery. Life may be endangered if there is profuse bleeding or compression of

the lungs and great vessels or if infection occurs

*Clinical Features*.—Bleeding from the lung usually ceases in from 24 to 48 hours, when the intrapleural pressure becomes greater than that of the injured vessel. Time should therefore be given for the tear of the lung to seal spontaneously. Anti-shock therapy should be administered in the meantime, with supportive treatment. Secondary bleeding may take place soon after the first 24 hours because of compression of the lung and blood vessels, especially in the presence of a pneumothorax. *This should be prevented if possible.* If the first pleural effusion has not been evacuated before this occurs, the interpleural pressure may cause dangerous compression symptoms.

The physical signs of hemothorax, except for shock and collapse, are similar to those of hydrothorax. Progressive bleeding is evident from pallor, restlessness, thirst, increase in pulse rate and decrease in blood pressure. Displacement of the apex of the heart and dullness of the chest to percussion are important symptoms.

When the hemothorax becomes infected, symptoms of infection arise suddenly. *A diagnostic aspiration should be made and* antibiotic therapy administered.

*Treatment*.—Treatment consists in control of shock and hemorrhage by use of morphine, *blood and plasma transfusions and oxygen*. Unless these measures are successful in from 36 to 48 hours, measures must be taken to produce evacuation of the collected blood, *re-expansion of the lung and obliteration of* the cavity as rapidly as possible. If the bleeding is from an intercostal or mammary artery, ligation may be necessary. If from a hilar vessel or from deep laceration of the lung, suturing may be required, or in extreme cases lobectomy. If the hemothorax becomes purulent, underwater drainage should be used. Rib resection is often found necessary in cases of infected hemothorax.

Decortication of the organizing hemothorax has become an accepted procedure. In many cases, however, use of streptokinase (SK) and streptodornase (SD) may liquify the coagulum and permit its removal by aspiration. *Although it must be considered* as an adjunct to surgical management, in some cases it may make decortication unnecessary. Antibiotics are generally administered at the same time.

### Chylothorax

Chylothorax, a disease in which chyle is present in the pleural cavity, is usually caused by a traumatic rupture of the thoracic duct. Occasionally, it is a result of occlusion of the thoracic duct by lymphoblastoma or of various diseases, such as *pressure-producing inflammation of endo*-thoracic lymph nodes, perforating lymphadenitis, Hodgkin's disease, cirrhosis of the liver, filariasis, and ruptured aneurysm of the thoracic duct. On rare occasions chylothorax occurs subsequent to intrathoracic surgical injury of the thoracic duct. Although chylothorax is usually on the right side (except in cases due to penetrating injuries, which are more common on the left side), it may occur bilaterally.

The aspirated fluid is milky in appearance and has a fat content of from 0.4 to 4.0 per cent. The chyle is bacteriostatic and therefore resists putrefaction. It is rich in lymphocytes, *but the lymphocytes in the blood are* decreased.

*Clinical Manifestations*.—The disease is characterized by rapid onset with severe *symptoms which, however, are quickly* relieved by thoracentesis. In addition to the symptoms attendant upon any rapid pleural effusion, weight loss from malnutrition, *oliguria* and thirst occur. Without replacement of the lost fluid protein and fat, wasting and exhaustion may cause death within a few days or weeks. In some cases a partial equilibrium is established and though the patient does not regain his lost weight, further loss does not take place. The patient may then live in fairly good health for years. Many patients recover after simple aspiration of the fluid.

When suction drainage fails to bring about re-expansion of the lung and stoppage of chyle within from 10 to 14 days and the patient presents *a downhill course, surgical* ligation of the thoracic duct is indicated. Simple ligation should be sufficient to stop the loss of chyle permanently. Roentgen

therapy may be temporarily helpful in cases caused by lymphoblastoma of the mediastinum A high protein diet intravenous infusion of amino acids and an occasional blood transfusion are recommended

## DISEASES OF THE MEDIASTINUM

By J WINTHROP PEABODY M D and
J WINTHROP PEABODY JR M D

### MEDIASTINAL EMPHYSEMA

*Etiology* —Air may gain access to the mediastinum by a number of routes Chest injuries with wounds of the trachea major bronchi or esophagus may lead to massive mediastinal emphysema Infection foreign bodies and instrumentation which cause perforation of the same organs from within may produce mediastinal emphysema Surgery on the neck or cervical lacerations may permit air to dissect into the mediastinum and perforating injuries of the abdomen pneumoperitoneum and perirenal air insufflation have occasionally introduced air into the retroperitoneal space and thence into the mediastinum

In most cases no obvious etiologic factors are demonstrable Macklin has established the following chain of events in the usual cases increased intra-alveolar pressure rupture of an alveolus pulmonary interstitial emphysema entry of air into the mediastinum by dissecting along the perivascular sheaths of pulmonary vessels Invariably no basic lung pathology is demonstrable hence the term *spontaneous mediastinal emphysema* The condition may follow exertion as in childbirth but usually occurs while the victim is at rest

*Signs and Symptoms* —The complaints are usually a sudden onset of substernal pain radiating to the back or into the left shoulder and mimicking coronary thrombosis even to the point of radiating in rare instances down the arm to the fourth and fifth fingers of the left hand The pain is more often mild and unaccompanied by evidence of respiratory distress but with increasing *degrees of pressure within the mediastinum* the great veins collapse cardiac output is diminished and dyspnea and cyanosis appear The occurrence of such degrees of intramediastinal tension is commonly averted by the escape of air through intercommunicating fascial planes Inasmuch as the pretracheal and prevertebral fascia of the neck are continuous at their inferior margins with the anterior and posterior walls respectively of the mediastinum entry of air into the neck occurs with subsequent dissection through the subcutaneous planes of the body Pain in the chest has occasionally been observed to subside with the appearance of subcutaneous emphysema Another frequently associated finding is a spontaneous pneumothorax usually on the left resulting from a small rent in the mediastinal pleura This has raised the question of whether many spontaneous pneumothoraces may not be secondary to mediastinal emphysema

The *Hamman s sign of mediastinal* emphysema is a peculiar crunching or crackling sound synchronous with the heart beat This sound is due to compression by the *heart of the mediastinal air pockets overlying* the heart In fact the air over the heart

the lungs and great vessels, or if infection occurs

*Clinical Features.*—Bleeding from the lung usually ceases in from 24 to 48 hours when the intrapleural pressure becomes greater than that of the injured vessel. Time should therefore be given for the tear of the lung to seal spontaneously. Anti-shock therapy should be administered in the meantime, with supportive treatment. Secondary bleeding may take place soon after the first 24 hours because of compression of the lung and blood vessels, especially in the presence of a pneumothorax. This should be prevented if possible. If the first pleural effusion has not been evacuated before this occurs, the interpleural pressure may cause dangerous compression symptoms.

The physical signs of hemothorax, except for shock and collapse, are similar to those of hydrothorax. Progressive bleeding is evident from pallor, restlessness, thirst, increase in pulse rate and decrease in blood pressure. Displacement of the apex of the heart and dullness of the chest to percussion are important symptoms.

When the hemothorax becomes infected, symptoms of infection arise suddenly. A diagnostic aspiration should be made and antibiotic therapy administered.

*Treatment.*—Treatment consists in control of shock and hemorrhage by use of morphine, blood and plasma transfusions, and oxygen. Unless these measures are successful in from 36 to 48 hours, measures must be taken to produce evacuation of the collected blood, re-expansion of the lung, and obliteration of the cavity as rapidly as possible. If the bleeding is from an intercostal or mammary artery, ligation may be necessary. If from a hilar vessel or from deep laceration of the lung, suturing may be required or, in extreme cases, lobectomy. If the hemothorax becomes purulent, underwater drainage should be used. Rib resection is often found necessary in cases of infected hemothorax.

Decortication of the organizing hemothorax has become an accepted procedure. In many cases, however, use of streptokinase (SK) and streptodornase (SD) may liquefy the coagulum and permit its removal by aspiration. Although it must be considered as an adjunct to surgical management, in some cases it may make decortication unnecessary. Antibiotics are generally administered at the same time.

## CHYLOTHORAX

Chylothorax, a disease in which chyle is present in the pleural cavity, is usually caused by a traumatic rupture of the thoracic duct. Occasionally, it is a result of occlusion of the thoracic duct by lymphoblastoma or of various diseases such as pressure-producing inflammation of endothoracic lymph nodes, perforating lymphadenitis, Hodgkin's disease, cirrhosis of the liver, filariasis, and ruptured aneurysm of the thoracic duct. On rare occasions chylothorax occurs subsequent to intrathoracic surgical injury of the thoracic duct. Although chylothorax is usually on the right side (except in cases due to penetrating injuries, which are more common on the left side), it may occur bilaterally.

The aspirated fluid is milky in appearance and has a fat content of from 0.4 to 4.0 per cent. The chyle is bacteriostatic and therefore resists putrefaction. It is rich in lymphocytes, but the lymphocytes in the blood are decreased.

*Clinical Manifestations.*—The disease is characterized by rapid onset with severe symptoms which, however, are quickly relieved by thoracentesis. In addition to the symptoms attendant upon any rapid pleural effusion, weight loss from malnutrition, oliguria and thirst occur. Without replacement of the lost fluid protein and fat, wasting and exhaustion may cause death within a few days or weeks. In some cases a partial equilibrium is established and, though the patient does not regain his lost weight, further loss does not take place. The patient may then live in fairly good health for years. Many patients recover after simple aspiration of the fluid.

When suction drainage fails to bring about re-expansion of the lung and stoppage of chyle within from 10 to 14 days and the patient presents a downhill course, surgical ligation of the thoracic duct is indicated. Simple ligation should be sufficient to stop the loss of chyle permanently. Roentgen

ally shows a marked leucocytosis (15 000 to 30 000 leucocytes), with a significant shift to the left

*Treatment* —Massive amounts of antibiotics should be used Adequate dependent drainage is essential and is of particular value in the case of mediastinal abscesses This drainage may sometimes be effected through a cervical or paravertebral incision If the esophagus is perforated the patient must be kept in the Trendelenburg position with continuous suction at a point just above the perforation—and in the opinion of some with a gastrostomy below—to permit administration of food and fluids

*Chronic Mediastinitis* —*Definition* — Chronic mediastinitis is an uncommon disease in which the normal mediastinal areolar tissue is largely replaced by a dense network of fibrous connective tissue Distortion of the mediastinum results with pressure on the various enclosed structures

*Etiology* —Tuberculosis is by far the most common cause of this condition as the result of massive mediastinal node involvement Syphilis once contributed a significant number of cases of the same sort but this is no longer true By direct extension into the mediastinum actinomycosis blastomycosis and other pulmonary mycoses may produce extensive mediastinal fibrosis Finally chronic mediastinitis may in some instances represent the effects of an acute mediastinitis

*Signs and Symptoms* —As a result of the traction upon and compression of the trachea bronchi esophagus nerves and great veins a wide variety of symptoms may arise Substernal pain dyspnea chronic cough dysphagia hoarseness hiccough and superior vena-cava syndrome may appear

*Diagnosis* —The history and symptomatology are of considerable value in establishing a diagnosis of chronic mediastinitis Physical examination is not rewarding X rays reveal widening and increased density of the superior mediastinum plus numerous adhesions and extensive fibrosis involving the diaphragm the pericardium the pleural sac *etc*

*Treatment* —Therapy consists of treatment of the primary cause

## DISEASES OF THE DIAPHRAGM

BY J WINTHROP PEABODY M D and J WINTHROP PEABODY JR M D

The diaphragm is the dome-shaped striated musculo-tendinous partition serving as the primary muscle of respiration and as a secondary muscle in venous return as well as separating the thoracic from the abdominal cavity

The embryologic derivation of the diaphragm is a fairly complex matter The anterolateral segment is derived from the septum transversum which in the early embryo originates in the cervical region (explaining the cervical innervation of this muscle via the phrenic nerves) The posterolateral portion of the diaphragm is derived from the pleuroperitoneal membrane and to some extent from the dorsal mesentery These structures eventually fuse but various malformations may result *e g* failure of the pleuroperitoneal membrane to develop (congenital absence of a part of the diaphragm) failure of the pleuroperitoneal membrane to fuse with the septum transversum (foramen of Bochdalek) weakness in

may obliterate the usual dullness obtained on percussion over the heart. Hamman's sign is pathagnomonic of mediastinal emphysema.

*Diagnosis.*—The most reliable diagnosis is clinical. X-ray examination may be confirmatory.

*Treatment.*—In severe cases a collar incision just above the manubrium through the deep cervical fascia may be lifesaving. Tracheotomy is never indicated, since vena-cava compression, rather than tracheal compression, is the source of the dyspnea and cyanosis. Milder cases require no particular therapy and may be followed on an ambulatory basis. The patient should be instructed to avoid coughing, straining at stool, *etc.*, so as not to increase the intra-alveolar pressure. A cough depressant may be indicated. Chemotherapy should be used only in the presence of active infection, not as a prophylactic measure.

## MEDIASTINITIS

*Acute Mediastinitis.—Definition and Etiology.*—Acute mediastinitis is never a primary disease but is always secondary either to primary infection elsewhere or to perforation of the esophagus or tracheobronchial tree. Esophageal injury is certainly the most common cause, it being responsible for about half of cases. It may result from such procedures as esophagoscopy, gastroscopy, and attempts at dilatation or from the ingestion of sharp foreign bodies, of which fish and chicken bones are by far the commonest. Less often, perforation results from esophagitis or carcinoma. Though the fragile wall of the esophagus predisposes to perforation, the sturdier structures of the trachea and bronchi reduce the possibility of rupture.

The next most common cause of acute mediastinitis is infection of the neck, which occurs predominantly in children. When mediastinitis is secondary to cervical or lung infection, the offending organism is chiefly a hemolytic streptococcus.

*Pathology.*—Since perforations fo the esophagus are more often at the pharyngoesophageal junction and most infections descend from the neck, the superior mediastinum is the more frequent location of acute mediastinitis. Both localized and diffuse forms of the disease occur; the localized form, the more common, is known as mediastinal abscess, the diffuse form is known as acute suppurative (phlegmonous) mediastinitis.

Acute suppurative mediastinitis may be accompanied by rapid extension of suppuration with little tendency toward localization or respect for anatomical boundaries. The entire mediastinum becomes bathed in pus. Although this kind of acute mediastinitis is more apt to follow cervical infection than esophageal perforation, it may nevertheless result from other causes. Penetration of the lung is not seen, but bilateral empyemas frequently occur from extension of the disease along peribronchial connective sheaths to the subpleural lymphatics.

*Signs and Symptoms.*—Sudden cervical or substernal pain upon swallowing a few hours after esophageal instrumentation or the ingestion of a foreign body is the classical picture of acute mediastinitis and is clearly elicited in a surprising number of instances.

All degrees of severity are encountered. Pain, the main symptom, is often intensified by swallowing and may indicate by its location the level of mediastinitis. There is usually a rather severe systemic toxicity. Such symptoms as brassy cough, hiccough, hoarseness, hyperpnea, and stridor may occur. The disease may be fulminating and rapidly fatal. If it is, prostration, high fever and evidence of venous compression (dyspnea and cyanosis) are found. Otherwise evidence of venous compression is unusual.

Physical examination is only of limited value. Anterior displacement of the trachea can sometimes be demonstrated (inability to insert the finger behind the suprasternal notch). Percussion may reveal a widened area of dullness overlying the mediastinum. Signs in the neck include tenderness, fullness, heat, and subcutaneous emphysema. There may be severe pain on moving the trachea. Occasionally evidence of mediastinal emphysema will be found.

*Diagnosis.*—In addition to the physical findings, a great deal may be learned from *x*-ray study. Examination of the blood usu-

ties constitute about 70 per cent of all diaphragmatic hernias.

(3) *Short Esophagus Type* (true thoracic stomach). — As the term implies, this type of diaphragmatic hernia is dependent upon a short esophagus, that is, an esophagus of insufficient length to permit the stomach to lie completely below the diaphragm. It may be congenital in origin or acquired by contraction secondary to chronic inflammation. Unlike the other types, this kind of hernia cannot reduce itself, for it is fixed, not sliding. The esophagus terminates at the very apex of the stomach. About 8 per cent of diaphragmatic hernias fall into this group.

*Signs and Symptoms.* — Many cases are asymptomatic. When present, clinical manifestations may vary with the size and reducibility of the hernia, but one cannot help being impressed by the frequency with which severe symptoms arise from a small hernia. In such instances the element of diaphragmatic muscle spasm around the hiatus is undoubtedly of great importance.

A vague sense of mild epigastric distress, variously described as a "fullness," "heartburn," "indigestion," or actual pain, is the usual chief complaint. The classic picture is the occurrence of such pain during or following a heavy meal, with aggravation upon lying down or stooping over, followed on some occasions by relief from belching, vomiting, or by merely walking about. The pain may be primarily nocturnal in occurrence and prevent the patient from sleeping in the recumbent position. Diaphragmatic spasm may produce referred pain in the left neck, shoulder, or down the arm. Couple such symptoms with substernal oppression, a rapid pulse and palpitation due to a slight displacement of the heart from the hernia, and it is easy to see how an erroneous diagnosis of angina pectoris can be made. Harrington found the most frequent errors in diagnosis to be gall bladder disease and peptic ulcer.

Regurgitation or gaseous eructation may be the sole complaint, but again characteristically follows meals and is apt to be precipitated by reclining or bending over, although satisfactory egress of gas and gastric contents may be impeded by concomitant spasm of the diaphragm. The patient may be aware of a gurgling sound within the chest on deep inspiration. Not infrequently the severe case leads to such an association of pain and vomiting with meals that the patient develops "food fear," limits himself to a very small dietary intake, and loses weight.

Esophagitis, gastritis, or ulceration may result from reflux of acid gastric contents, sliding motion of the hernia, or constriction from the diaphragmatic spasm. The associated dysphagia may be severe. Profuse hematemesis and melena are uncommon, but the persistent presence of occult blood in the stool will often produce a moderate secondary anemia.

With large hernias, respiratory or cardiac embarrassment may occur. If the colon is involved in the hernia, obstipation and evidence of intestinal obstruction may result.

*Diagnosis.* — Esophageal hiatus hernias may be suspected on routine chest films, but the definite diagnosis depends upon *x*-ray and fluoroscopic studies after ingestion of an opaque material. By coating the esophagus and stomach with a thin coat of barium several pertinent findings can be obtained.

X-ray is of assistance in ruling out other conditions, including *eventration of the diaphragm*. The latter is a rare condition of unknown etiology characterized by an atonic elevated hemidiaphragm which, on gross examination, proves to be thin, translucent, and similar to the diaphragm that has been paralyzed. It is characteristically asymptomatic but may be associated with vague gastrointestinal or respiratory symptoms. More often than not it is merely an incidental finding, giving the picture of a high curved leaf of the diaphragm, usually on the left, hence having the gas bubble of the stomach immediately below. The striking fluoroscopic finding is that found with any paralyzed diaphragm, namely, paradoxical ascent (rather than descent) of the involved hemidiaphragm on inspiration. This is caused by the relative increase in intra-abdominal pressure during inspiration, with the result that the relaxed diaphragm is pushed upward while the normal leaf contracts downward. Barium swallow will prove negative in cases of eventration, which may afford the only means of differentiating

61

or enlargement of the foramen of Morgagni, and, finally defects in the esophageal hiatus One type of the latter may result from an esophagus which failed to grow to a sufficient length to permit the stomach to occupy *its normal position below the diaphragm* (thoracic stomach)

*Dysfunction of the Diaphragm* —This manifests itself in abnormal position of the diaphragm The position which it takes under normal as well as pathologic conditions depends in the first place upon its own tonus which overcomes both the positive intra abdominal and the negative intrathoracic pressures Since the tonus changes in the diaphragm depend upon the pressure differences between the thoracic and abdominal cavities this difference will have its influence upon the position of the diaphragm When it loses its tonus its position will come to depend altogether upon these differences in the pressure in the two cavities The *toneless diaphragm will be sucked up into* the chest with every inspiration and left to flop back in every expiration (paradoxical movements in diaphragmatic palsy) It may on the other hand be pushed down into the abdomen by increased intrathoracic pressure such as occurs in pulmonary emphysema pneumothorax or pleural effusions

*Elevation of the diaphragm* will thus be observed under the following circumstances (1) in the presence of increased abdominal pressure as in ascites or meteorism This is particularly the case if the abdominal pressure increases abruptly while slow *increase* of abdominal pressure such as occurs in pregnancy or abdominal tumors may be compensated for a long time by elevation of the lower ribs and increase of the diaphragmatic tonus (2) in the presence of increased thoracic pull such as is exerted by retractive processes in the lungs and pleura or pulmonary collapse (3) in the presence of reduced diaphragmatic tonus such as occurs in relaxation of the diaphragm whether congenital or acquired or in phrenic nerve palsy

The most frequent *form of elevation of* the diaphragm due to reduced tonus is that arising in paralysis of the phrenic nerve which is now so frequently produced artificially as a method of treatment in various pulmonary diseases, particularly tuberculosis

Descent of the diaphragm on the other hand, will be observed under the following circumstances (1) decreased thoracic suction as occurs in some cases of emphysema, of asthma, and in pleural effusion (2) decreased abdominal pressure such as is seen in general visceroptosis (3) increased diaphragmatic tonus associated with diaphragmatic spasm in such nervous disorders as hiccough encephalitis tetanus and in some cases of poliomyelitis

## ORGANIC DISEASES OF THE DIAPHRAGM

DIAPHRAGMATIC HERNIA —Herniation of abdominal viscera into the thorax may result either from defects in the normal diaphragmatic openings or from abnormal openings due to congenital malformation or trauma

*Esophageal Hiatus Hernia* —Herniation through the esophageal hiatus constitutes the major source of diaphragmatic hernias in adults Many are completely asymptomatic being picked up as incidental findings in *x* rays for other purposes Brick found an incidence of slightly over 300 hiatal hernias in one series of 3500 consecutive upper gastrointestinal series It was once thought to involve predominantly females preferably fat multiparous ones but this predilection appears exaggerated Several types occur

(1) *Paraesophageal Type* —Here the esophagus is of normal length with the lower end fixed below the diaphragm while a small portion of the gastric cardia herniates through the hiatus alongside the esophagus into the posterior mediastinum

(2) *True Hiatus Hernia* —With this type the esophagus is of normal length but not only the stomach is found to have ascended above the diaphragm but also the distal portion of the esophagus Moreover the amount of stomach above the neck of the hernia is usually larger than with the para esophageal type so that it has been proposed that the true hiatus hernia represents perhaps a more advanced stage of the paraesophageal hernia Together these two varie-

ties constitute about 70 per cent of all diaphragmatic hernias

(3) *Short Esophagus Type* (true thoracic stomach) — As the term implies this type of diaphragmatic hernia is dependent upon a short esophagus that is an esophagus of insufficient length to permit the stomach to be completely below the diaphragm It may be congenital in origin or acquired by contraction secondary to chronic inflammation Unlike the other types this kind of hernia cannot reduce itself for it is fixed not sliding The esophagus terminates at the very apex of the stomach About 5 per cent of diaphragmatic hernias fall into this group

*Signs and Symptoms* — Many cases are asymptomatic When present clinical manifestations may vary with the size and reduceability of the hernia but one cannot help being impressed by the frequency with which severe symptoms arise from a small hernia In such instances the element of diaphragmatic muscle spasm around the hiatus is undoubtedly of great importance

A vague sense of mild epigastric distress variously described as a fullness heart burn' indigestion or actual pain is the usual chief complaint The classic picture is the occurrence of such pain during or following a heavy meal with aggravation upon lying down or stooping over followed on some occasions by relief from belching vomiting or by merely walking about The pain may be primarily nocturnal in occurrence and prevent the patient from sleeping in the recumbent position Diaphragmatic spasm may produce referred pain in the left neck shoulder or down the arm Couple such symptoms with substernal oppression a rapid pulse and palpitation due to a slight displacement of the heart from the hernia and it is easy to see how an erroneous diagnosis of angina pectoris can be made Harrington found the most frequent errors in diagnosis to be gall bladder disease and peptic ulcer

Regurgitation or gaseous eructation may be the sole complaint but again characteristically follows meals and is apt to be precipated by reclining or bending over although satisfactory egress of gas and gastric contents may be impeded by concomitant spasm of the diaphragm The patient may be aware of a gurgling sound within the chest on deep inspiration Not infrequently the severe case leads to such an association of pain and vomiting with meals that the patient develops food fear limits himself to a very small dietary intake and loses weight

Esophagitis gastritis or ulceration may result from reflux of acid gastric contents sliding motion of the hernia or constriction from the diaphragmatic spasm The associated dysphagia may be severe Profuse hematemesis and melena are uncommon but the persistent presence of occult blood in the stool will often produce a moderate secondary anemia

With large hernias respiratory or cardiac embarrassment may occur If the colon is involved in the hernia obstipation and evidence of intestinal obstruction may result

*Diagnosis* — Esophageal hiatus hernias may be suspected on routine chest films but the definite diagnosis depends upon $x$ ray and fluoroscopic studies after ingestion of an opaque material By coating the esophagus and stomach with a thin coat of barium several pertinent findings can be obtained

X ray is of assistance in ruling out other conditions including *eventration of the diaphragm* The latter is a rare condition of unknown etiology characterized by an atonic elevated hemidiaphragm which on gross examination proves to be thin translucent and similar to the diaphragm that has been paralyzed It is characteristically asymptomatic but may be associated with vague gastrointestinal or respiratory symptoms More often than not it is merely an incidental finding giving the picture of a high curved leaf of the diaphragm usually on the left hence having the gas bubble of the stomach immediately below The striking fluoroscopic finding is that found with any paralyzed diaphragm namely paradoxical ascent rather than descent of the involved hemidiaphragm on inspiration This is caused by the relative increase in intra abdominal pressure during inspiration with the result that the relaxed diaphragm is pushed upward while the normal leaf contracts downward *Barium swallow* will prove negative in cases of eventration which may afford the only means of differentiating

one condition from the other. Although eventration was once viewed with some alarm, we have now learned not to get excited over any degree of diaphragmatic rise and may in fact try to increase such a rise in patients with pulmonary cavitation by the induction and maintenance of an artificial pneumoperitoneum.

*Treatment.*—Medical management is possible in many mild cases and is advisable in elderly patients with minimal if any complaints. *A bland diet of nonbulky small* meals may afford relief. Antacids, antispasmodics and sedatives may obtain dramatic results and are of particular merit in the presence of esophagitis or ulceration. If strictures should be found, and it is especially important to rule them out by esophagoscopy, careful dilatation will often obtain a considerable amelioration of symptoms. When distressing complaints persist despite an ulcer regime and these other measures it is necessary to resort to surgery.

*Congenital Diaphragmatic Hernias.*—With the exception of diaphragmatic hernias following trauma and the small paraesophageal hernias following atrophy of the diaphragmatico-esophageal membrane practically all diaphragmatic hernias are dependent upon an element of congenital maldevelopment. Less definite in this regard are the esophageal hiatus hernias and those through the foramen of Morgagni, both of which tend to wait until middle age before *presenting themselves*. On this account these two types have, for descriptive purposes, been discussed previously. There remains a group in which the diaphragmatic *defects are larger and the symptoms much* earlier in onset so that the embryologic factor is quite striking. These have therefore been grouped under the heading of congenital hernias *and include primarily* those through the foramen of Bochdalek.

*Traumatic Diaphragmatic Hernias.*—Rents in the diaphragm may result from direct laceration as from a knife, *bullet or other* missile, or may result from indirect rupture due to crushing injuries of the chest or abdomen. Because of the liver barrier on the right most lesions occur on *the left*. Subphrenic abscesses are a rather common inflammatory source of diaphragmatic openings but do not lead to difficulty from herniation since they are on the right. A drainage tube in an empyema cavity has occasionally produced erosion *through the diaphragm*.

## ACUTE PRIMARY DIAPHRAGMITIS (HEDBLOM'S SYNDROME)

Acute primary diaphragmitis or Hedblom's syndrome is a primary myositis of the diaphragm seen after chilling or acute *infections of the upper respiratory tract*. It bears no relation to lesions of the diaphragmatic pleura, the lower lobes of the lung or the subphrenic organs, but lesions in these areas may follow as sequelae *of Hedblom's* syndrome. Clinically it is manifested by the presence of inspiratory pain in the lower chest, pain that cuts short the respiratory effort and prevents the patient from breathing beyond a certain depth. The respirations have a tendency to become costal in type and there is a limitation in the expansion of the lower portion of the chest wall. There is also a spasm of the abdominal muscles just below the costal margin with pain along the upper quadrants of the abdomen but no deep tenderness. The costal margin flares out and remains immobile. The patient generally complains of a re*ferred pain in the shoulder*, the trapezius ridge, and the supraclavicular area, pain caused by impulses through the phrenic and the related cervical nerves. Fluoroscopically *the diaphragm remains in a state of immobilization* in the midposition between inspiration and expiration. As the acute myositis subsides the muscle fibers may be replaced *by fibrous tissue and cause a flattening* out of the diaphragm, a flattening that has persisted for as long as thirteen years after the patient's recovery from the acute symptoms. *The inflammation may extend to the* diaphragmatic pleura and the subphrenic peritoneum, thus causing complications.

*Trichiniasis* is an important consideration *in the differential diagnosis because of the* primary diaphragmatic myositis due to involvement from the migrating trichinella larvae.

*Pleurodynia has often been confused* with Hedblom's syndrome. This condition is related to myositis of the intercostal muscles

and bears no relation to the diaphragm. It is characterized by constricting pain in the intercostal spaces and is aggravated by breathing. The same findings may also be found in *intercostal neuralgia* and *herpes zoster intercostalis*. Hedblom's syndrome is a self-limiting disease and clears up after one or two weeks. The treatment is symptomatic.

Secondary diaphragmitis may result from lesions in the lower lobe of the lung or in the subphrenic areas and cause symptoms similar to those of Hedblom's syndrome. In such cases the preexisting primary lesion is usually obvious.

BRONCHIAL TUMORS

*Bronchiogenic Carcinoma.*—Once regarded as a lesion of rare occurrence, this neoplasm now rivals gastric carcinoma as the most common malignancy in man.

Two developments have undeniably tended toward the detection of a proportionately greater number of cancers of the lung: improved diagnostic facilities (x-ray, bronchoscopy, cytology) and better insight into the pathology of pulmonary neoplasms, many of which were formerly regarded as primary mediastinal tumors or tumors metastatic to the lung. Many, too, were obscured by overwhelming intercurrent infections that now respond to antibiotics.

*Incidence.*—Bronchiogenic carcinoma constitutes more than 10 per cent of all cancers found at autopsy. It is much more frequent in males than in females, the difference being at least 4:1 and in most recent series considerably higher. We must remember that the patient's age does not rule out the disease.

*Pathology.*—Histologically, bronchiogenic carcinomas are notorious for their extreme cellular pleomorphism. Nevertheless, it is possible in most instances to classify them according to the predominating cell type.

(1) *Epidermoid (squamous cell) carcinoma,* the most common type, consists of flattened epithelial cells arranged in concentric masses exhibiting varying degrees of keratinization with or without associated pearl formation. Although they are highly malignant, the epidermoid carcinomas tend to be slower growing than the other varieties and their local invasive propensities appear to overshadow their tendency toward distant metastasis. Because they most often involve large bronchi, the initial involvement is primarily hilar, with secondary invasion of the lung parenchyma and mediastinum.

(2) *Adenocarcinoma* (cylindrical-cell carcinoma) consists of cylindrical or columnar epithelial cells characteristically, though far from constantly, arranged in glandular patterns and sometimes showing evidence of mucin production (colloid type of adenocarcinoma). About 50 per cent of these tumors arise in the periphery of the lung. Early widespread metastases are common place. Probably the most striking clinical feature is the reversal of the sex incidence, women being involved equally as often as men and in some series even more often (Fried).

(3) *Undifferentiated* (anaplastic) carcinomas of the lung consist of a variety of cell types, namely, the round, the oat, and the spindle types. All have a scant cytoplasm and appear closely related one to the other. In each, the cells are usually closely packed and have a minimum of intervening stroma. This group shows the most rapid growth with a distinct predilection for early medias-

tinal invasions and wild lymphogenous and hematogenous dissemination

Insofar as the gross characteristics of these tumors are concerned there are no features that distinguish one type of bronchogenic cancer from another About 80 *per cent of* the tumors originate within the hilar portion of the bronchial tree and 20 per cent in the periphery The right lung is somewhat more often affected than the left

The spread of bronchiogenic carcinoma occurs in four known ways by direct ex-and inferiorly to the diaphragm, through which it may erode A rich network of lymphatics *interlaces the pulmonary paren* chyma to account for lymphogenous spread between lobes (this occurs often enough to *render simple lobectomy an inadequate* mode of therapy) By the time they are discovered about 75 per cent of the cases also show lymphatic extension to regional lymph nodes The bronchopulmonary nodes are first invaded then the tracheobronchial and paratracheal nodes (So frequently are

Fig 159 —Bronchiogenic carcinoma

tension by lymphogenous metastasis by hematogenous metastasis and by aerogenous spread Direct extension may take place in any direction *Because of the* predominantly hilar origin of bronchiogenic carcinoma the mediastinum is most often involved, and this entails encroachment on a variety of vital organs The more peripheral lesions may extend centrifugally to invade the pleura and thoracic wall superiorly to involve the brachial plexus, cervical sympathetics and other structures in the neck

the nodes involved that any attempt at curative surgery absolutely demands a thorough resection of them in addition to pneumonectomy *even though no spread* is apparent) Further lymphogenous dissemination follows the supradiaphragmatic abdominal retroperitoneal iliac, cervical, supraclavicular axillary and other lymphatic chains *The hematogenous route* is of the utmost importance and undoubtedly accounts for most of the metastasis to the contralateral *lung liver brain* skeletal

system adrenals and kidneys although lymphatic connections with the last two have definitely been demonstrated The aerogenous spreading of the exfoliated malignant cells is most unlikely

Massive metastasis may originate in a small primary lesion The most common sites of metastasis are the regional nodes (75 per cent) the liver and the contralateral lung (30 per cent) the bones the central nervous system, the adrenals and the kidneys (about 20 per cent) and the pericardium and the heart (15 per cent)

*Clinical Course* —The onset of bronchogenic cancer is usually insidious and has been frequently referred to as the silent phase because of the complete lack of symptoms Depending upon the size location and direction of growth a heterogenous group of symptoms soon appear Bronchial irritation leads to an irritative cough ulceration of the bronchial mucous membrane to hemoptysis Endobronchial growth results in partial obstruction of air flow manifested by varying degrees of wheezing and dyspnea If the mass should develop a ball-valve character, emphysema develops distal to the obstruction by permitting the entrance but preventing the exit of air Restricted drainage of normal secretions also occurs and leads to secondary suppurative disease peripherally Where obstruction becomes complete atelectasis of the occluded segment or lobe results

*Symptoms* —*Cough* is usually the first symptom to manifest itself and eventually accompanies practically every case Many individuals actually have a chronic almost lifelong cough and thus here a change in cough habit may be of great significance At first dry and irritative the cough later becomes productive as secretions pool behind the point of obstruction and in the event of infection becomes purulent and foul Eventually most patients show blood streaking It is to be stressed that until proved otherwise a persistent cough of unexplained origin occurring in a male patient of cancer age is prime evidence of bronchiogenic carcinoma In such an instance failure to obtain an *x* ray of the chest is inexcusable

*Hemoptysis* The sputum generally contains no more than streaks or flecks of blood When a copious quantity of blood occurs it is suggestive of adenocarcinoma Rienhoff has shown that hemoptysis and cough eventually occur in combination in 63 per cent of the cases

*Chest pain* is seldom an early complaint but ultimately occurs in 50 per cent of the cases and is one of the few things that will prompt the patient to obtain medical help Unlike pleurisy the pain is constant and unassociated with the respiratory cycle

*Weight loss* may be an impressive feature and accompanied by emaciation It may be out of all proportion to the size of the tumor or duration of the disease In fact it may be the initial sign but is usually relatively late

*Dyspnea* seldom occurs early but eventually appears in the majority of cases as the vital capacity is reduced by direct carcinomatous involvement of lung parenchyma and by such contributing factors as emphysema atelectasis infection pleural effusion and compression of the pulmonary artery and vein

*Unilateral wheezing* is an extremely valuable sign resulting from bronchial stenosis Not infrequently the wheezing is paroxysmal but can be brought out by forced expiration

In contrast to the aforementioned symptoms which are attributable to direct lung involvement there is a broad group of symptoms which result from metastasis When they occur in the absence of pulmonary symptoms they may present a most bizarre and puzzling picture

Mediastinal metastases may lead to involvement of the recurrent laryngeal nerve (hoarseness) especially on the left, where it traverses a longer course passing beneath the aortic arch involvement of the phrenic nerve (cervical pain and paralysis of the corresponding leaf of the diaphragm) compression or invasion of the esophagus (dysphagia) or invasion of the pericardium and heart (pericardial effusion or cardiac arrhythmias) Compression of the superior vena cava leads to the so-called superior-vena cava syndrome manifested by venous engorgement and cyanosis over the distribu

tion of the superior vena cava If acute, edema may be a prominent feature This syndrome usually occurs late and is of ominous significance

Extension through the superior thoracic strait may lead to a Pancoast syndrome, *consisting of ptosis of the upper eyelid* myosis, enophthalmus, anhidrosis and cutaneous flush (Horner's syndrome) due to cervical sympathetic nerve involvement along with pain and muscle atrophy in the shoulder girdle, arm, and hand due to brachial plexus invasion

Extension to the pleura may result in pleuritic pain or pleural effusion Such an effusion is classically sanguinous but need not be Malignant cells can generally be found in the sediment Not infrequently the pleura may be involved in sheetlike fashion similar to that described for pleural mesotheliomas (In fact, many of the reported mesotheliomas have been shown to be bronchiogenic cancers with an obscure primary site )

Diaphragmatic involvement particularly in the midportion may give rise to pain in the neck along the distribution of the phrenic nerve

Metastases to the central nervous system are predominantly cerebral and are quite common (about 20 per cent of cases) Similarly, of all metastatic malignancies in the brain those of pulmonary origin are by far the most common so much so that in *any case of an intracranial space occupying* lesion an *x* ray of the chest is mandatory

Metastases to bone occur in at least 20 per cent of the cases and probably in even more The vertebrae the ribs and the long bones appear to be affected in approximately that order of frequency Bone pain or a *pathologic fracture may accompany such* metastasis, but in other instances, the lesion may be completely silent and picked up only by a routine bone survey

Metastasis to the kidney may give rise to urinary symptoms such as hematuria Adrenal metastatic growths are usually small in size medullary in location and rarely give rise to signs of adrenal insufficiency

*Physical Signs* —Physical findings may be absent or scanty and are extremely variable depending upon the size and location of the tumor as well as on the degree of obstruction infection, effusion *etc* Almost any findings in the chest of a cancer age male must be closely checked for cancer, but physical findings alone are never diagnostic even in the presence of a unilateral wheeze *Pulmonary osteoarthropathy* is noted in 10 per cent of the cases and certainly should direct one to a study of the lungs It occasionally appears early but more often is a late sign

*Diagnosis* —The *sine qua non* of all early cancer detection is an awareness of its possible existence Nowhere does this aphorism find greater applicability than in the case of bronchiogenic carcinoma in which early symptoms appear trivial and are too often treated with indifference or at best with symptomatic therapy

1 *Roentgenography* although not without its shortcomings affords a *valuable diag*nostic implement

Body section radiography (tomography planography laminography) is of some value in confirming hilar lesions and should be utilized in any suspicious case Bronchography is rarely of value and may obscure future films

2 *Bronchoscopy* —It is now apparent that a positive bronchoscopy can be obtained in only about half of the cases Not only is it impossible to see most of the peripheral lesions by bronchoscopy but apical lesions even when seen are impossible to *biopsy Nevertheless the bronchoscope is* the best established means of obtaining a definite preoperative diagnosis Moreover, it may supply valuable information on the integrity of the vocal cords the proximity of the tumor to the trachea and the fixation of the trachea and evidence of carinal *involvement* (either directly or by an enlargement of a subcarinal node causing broadening of the angle of the carina) With the perfection of cytologic methods the aspiration of bronchial secretions from each lobe may give both a diagnosis and a location in an otherwise indiscernible case

3 *Cytology* is the newest diagnostic method and shows promise of becoming one of the best Specimens consist either of bronchial secretions obtained by bronchoscopy of sputum raised by deep cough Broncho-

scopic washings do serve more or less to localize a lesion but seem to exhibit no additional superiority whereas sputum has the advantage of being easily obtained This is of special significance for it has been shown that repeated studies of different specimens doubles the percentage of positive results Thus in only 35 per cent of all cases will one cytologic study confirm the diagnosis whereas 70 or 80 per cent of the cases will be confirmed by a series of five such examinations In cases of upper lobe lesions and lesions in the periphery cytology appears to have the greatest value for in these the bronchoscope *is practically worthless* *Epidermoid* and adenocarcinoma types are much more readily picked up than the undifferentiated carcinomas in which the cells are difficult to distinguish from inflammatory round cells Excessive enthusiasm should be discouraged but one must admit that the most encouraging prospect for the early diagnosis of bronchiogenic carcinoma lies in further advances along this line

4 *Aspiration Biopsy* —Although a fair percentage of positive results attend this method the hazard of carcinomatous seeding along the line of the needle puncture is sufficiently real to nullify whatever good results are obtained Other dangers such as hemoptysis infection and pneumothorax also exist Furthermore placing any confidence in a negative report might well lead in some cases to a disastrous delay in diagnosis

5 *Exploratory Thoracotomy* —In approximately 50 per cent of the cases no matter how exhaustive the workup a definite diagnosis cannot be established before operation Since operative surgery offers the sole means of diagnosing this group as well as the only chance of cure exploration in any given case appears justified on suggestive evidence alone so long as a comprehensive clinical investigation has been carried out

*Treatment* —*Pneumonectomy* with concomitant regional node dissection has been established as the treatment of choice *Lobectomy* is regarded as an inadequate procedure because it leaves behind adjoining lobes which may be simultaneously involved via the interconnecting lymphatics and because it hinders access to the mediastinal nodes which have been found to be involved at least microscopically in 75 per cent of the lungs resected The mortality rate from pneumonectomy for carcinoma runs about 15 per cent a relatively high figure but one that is continually decreasing and is actually somewhat lower in patients under 60 years of age Of all cases of bronchiogenic carcinoma probably about 15 per cent are resectable although various authorities publish a figure twice that Ochsner has demonstrated rather conclusively that the patients with palliative resections survive longer than those not considered for resection and *those who refuse resection* Moreover they are spared the element of sepsis and appear to die a less wretched death

The results of pneumonectomy depend almost entirely on the stage of the disease With localized malignancy the results are favorable Statistics show the survival rate following resection to drop precipitously for the first two years but to remain fairly level thereafter so that a patient who survives the second postoperative year stands a good chance of surviving 5 years Cases of epidermoid tumors stand the best chance for survival undifferentiated types the worst The conclusion is obvious that for eradication of the neoplasm diagnosis must be established early and surgical therapy applied quickly and vigorously

For patients considered inoperable *irradiation* may afford varying degrees of palliation Although the increased longevity is relatively brief in most instances it is enough to warrant irradiation in certain cases and a rare 5 year cure has been reported

*Nitrogen mustard* appears to offer symptomatic improvement in a relatively small percentage of cases but the improvement is transient and there is no significant prolongation of life Dramatic results with the drug have been described however in a number of cases of superior vena-cava syndrome

*Bronchial Adenoma* —Bronchial adenomas are uncommon tumors (about 5 per cent of all bronchial neoplasms) They may simulate bronchiogenic carcinoma although differing from the latter in several significant respects By contrast the bronchial aden

oma involves a younger age group, about half the reported cases having occurred in persons under 40, and affects the female more often than the male. Moreover, the adenoma typically runs a benign slow-growing course often marked by no more than a few symptoms. However despite the prolonged clinical course and amenability to bronchoscopic removal, one can no longer complacently refer to the lesion as benign. A few adenomas eventually undergo malignant degeneration to give rise to an undetermined but probably small percentage of bronchiogenic carcinomas. Of greater significance are the recent reports attesting to the occurrence of metastatic adenomatous involvement of mediastinal lymphnodes, liver, other organs and bone. In this light bronchial adenomas should more properly be considered carcinomas of low-grade malignancy.

Depending on the microscopic picture, two types of bronchial adenoma are described: the carcinoid adenoma (90 per cent of the cases) and the cylindroma or mixed type of tumor (10 per cent). The cylindromata are more apt to metastasize than the carcinoid adenomata.

The clinical picture is dependent on the degree of bronchial obstruction. The usual picture is that of a persistent aggravating cough which may be intensified on postural changes as on lying down and is more or less productive, this varying with the amount of secondary suppurative disease distal to the lesion. As one might anticipate from the richly vascular appearance of these tumors repeated episodes of hemoptysis usually occur and occasionally constitute the only symptom. A unilateral wheeze or recurrent bouts of respiratory infection are suggestive evidence in a young person. These tumors are slow growing but may eventually attain considerable size and then give rise to oppressive chest pain or dyspnea. Bronchiectasis or abscess formation may occur distal to the point of obstruction.

Bronchoscopic removal is possible when the lesion is pedunculated and free of extrabronchial extensions. Certainly, it is the only approach to adenomas involving the carina. In older persons, it may even be the procedure of choice but in general the age group in which adenomas are found renders the patients especially good candidates for resection. Resection also permits the obliteration of areas of secondary suppurative disease. Instances of local recurrence following bronchoscopic removal quite obviously demand lobectomy in all but extremely poor surgical risks.

*Hamartoma (Chondroma) of the Lung.*—Hamartomas are uncommon tumors occurring in various organs of the body. They consist of abnormal quantities and arrangements of the normal tissue structure of the organs they occupy. Thus chondromas of the lung are more appropriately referred to as hamartomas, containing as they do a preponderance of cartilaginous tissue in addition to other elements representative of normal bronchial wall. They are benign lesions but may mimic bronchiogenic carcinoma or echinococcic cyst. Surgical resection of the involved portion of the lung must be regarded as the only logical form of therapy.

*Hemangioma (Arteriovenous Fistula of the Lung).*—Hemangiomas of the lung are extremely rare tumors consisting predominantly of blood filled capillaries forming extensive intercommunications between the pulmonary artery and the pulmonary vein. A fair percentage are of the cavernous variety and serve as a pulmonary arteriovenous fistula.

*Clinical Course.*—The onset usually occurs in childhood. Males are affected more often than females. The characteristic picture is that of pulmonary osteoarthropathy, cyanosis and polycythemia in the presence of a pulmonary shadow of increased density on x-ray, but the shunt of blood may not be great enough to produce these signs. In about 50 per cent of the cases multiple telangiectasia and discrete hemangiomas of the skin and mucous membranes are present, often with a confirmatory history of epistaxis or gastrointestinal bleeding from a similar source in other members of the family. This relationship to Rendu-Osler-Weber disease is definite, the pulmonary hemangioma representing simply local evidence of a congenital tendency toward generalized malformation of the vascular system. Occasionally, auscultation over the location of the fistula will reveal a continuous bruit with accentua

tion in systole. The heart is normal but the electrocardiogram may show right axis deviation.

Angiocardiography seems to be the best diagnostic method and often shows rapid filling with delineation of the tumor.

Because of the many dangers attendant upon this lesion, surgical intervention is indicated in all but poor risk patients. Lobectomy is usually the method of choice.

*Alveolar Cell Carcinoma.*—(Pulmonary adenomatosis, malignant adenomatosis, diffuse primary alveolar carcinoma of the lung, carcinosis of the lung, terminal bronchiolar carcinoma.) Grossly, two types of pulmonary involvement have been described: a diffuse type wherein a picture resembling the stage of gray hepatization of lobar pneumonia may be found, with sticky surfaces similar to that of Friedländer's pneumonia; and a nodular type with multiple ill-defined nodular areas of consolidation somewhat like those seen with noncaseating miliary tuberculosis. No other primary tumor can be found elsewhere, thus ruling out the possibility of this representing metastatic involvement. In about 50 per cent of the cases the tumor is found localized in the lungs, usually without lymphatic extension; in the other 50 per cent, lymph node and/or visceral metastasis can be demonstrated.

The microscopic picture in alveolar-cell carcinoma consists of a striking hyperplasia of nonciliated mucus-secreting cuboidal or columnar epithelium lining otherwise unaltered alveolar walls. The most amazing feature is the presence of completely separate areas of obvious malignancy with preservation of intervening lung structure. Occasionally there is evidence of incipient hyperplasia in still another area.

Well worth noting is the close similarity of this entity to an epidemic virus disease of sheep called *jagziekte* or pulmonary adenomatosis. The histologic picture is identical but the cells are regular and metastases do not occur. Pulmonary adenomatosis of sheep is caused by a virus. While the latter has not been found pathogenic for man, the possibility of alveolar-cell carcinoma having some relationship to a virus is nevertheless an interesting consideration.

The clinical course of these patients is marked by a persistent cough which is dry initially but eventually becomes productive of copious quantities of a clear frothy sputum. This is fairly typical and depends upon increased output from the glandular cells of the alveoli. Dyspnea becomes prominent when a sufficient amount of functional alveolar lining is replaced by nonfunctional adenomatous tissue. Then extreme cyanosis occurs. Hemoptysis is notably absent in the majority of cases, as are fever and leucocytosis until the patient contracts a secondary infection. In the late stages cor pulmonale may occur, but pulmonary osteoarthropathy is seldom encountered.

The x-ray findings are in accord with the gross pathology. Attention should be devoted to the eosinophil count so as to rule out Loeffler's syndrome. Cytologic studies appear to be very rewarding.

No suitable form of therapy exists. Surgical intervention is of value in cases with unilateral involvement, and several 5-year cures have been reported following resection. The multicentric origin of these lesions, however, would appear to invalidate any claim for curative surgery. Irradiation and nitrogen mustard therapy have so far proved of no benefit.

### Mediastinal Tumors

*Teratoid Tumors (Teratomata and Dermoid Cysts).*—Teratoid tumors are uncommon tumors of embryonic origin. They probably arise as abnormal outgrowths of the third and fourth bronchial arches from which they separate to descend with the great vascular structures into the mediastinum. With the exception of lymphatic tumors, these are the most common neoplasms of the anterior mediastinum. They are most frequently of a cystic multilocu-lated type and may contain, in addition to undifferentiated cellular elements, vestigial structures such as hair, teeth, bone, *etc.* Solid teratoids are less often encountered but show a greater incidence of malignant changes. Some 70 per cent of all malignant teratoids arise from the solid variety.

In the majority of cases these tumors appear to lie dormant until puberty, when they

gradually begin to increase in size Radiologic evidence of the lesion can usually be demonstrated well in advance of the onset of symptoms Eventually the size and location of the tumor produce evidence of tracheal compression Resection is indicated on the basis of eventual malignant transformation of 12 per cent of cases

*Thymoma Thyroid Tumors Parathyroid Tumors* — See Chapter 16

*Neurogenic Tumors* — These constitute 90 per cent of all posterior mediastinal tumors and usually occur high in the paravertebral gutter

Other uncommon mediastinal tumors include *pericardial celomic cysts cystic hygromas bronchiogenic cysts gastroenterogenous cysts* and *tuberculomas* Rare instances of mediastinal *pheochromocytoma have been reported*

## Tumors of the Pleura

*Pleural mesothelioma* is a rare malignant tumor involving the pleura in a diffuse sheetlike manner and thereby surrounding and constricting although not invading the underlying lung Because some bronchiogenic carcinomas metastasize to the pleura in just such a fashion it has long been felt that reported cases of pleural mesothelioma probably originated in a small indiscernible primary site within the lung but enough well-documented cases have now been reported it seems to establish the authenticity of the true pleural mesothelioma

Grossly the pleura is markedly thickened and firm and grayish white in the areas of involvement which are usually fairly broad by time of discovery The visceral and parietal layers are both affected the pleural cavity being obliterated in some instances perfectly intact in others Pleural effusions are frequently encountered may be massive and are often bloody The lung exhibits varying degrees of atelectasis due to the constricting effect of the lesion but is usually not directly invaded By means of contiguous spread and serosal seeding the diaphragm peritoneum and pericardium often become studded with metastases Lymphatic metastasis to tracheobronchial mediastinal, retroperitoneal and cervical nodes are frequently encountered, and, in many instances the opposite pleura shows *involvement Occasionally* one encounters metastasis to the liver and other organs

Clinically, these tumors involve mainly the 40 to 60 year age group and occur about twice as often in males as in females The onset is insidious A nonproductive cough appears to be a common complaint Chest pain also frequently occurs early, is generally pleuritic and may be severe With loss of pleural elasticity, complete expansion is prohibited and dyspnea results This may be progressive and aggravated by pleural effusion Hilar adenopathy causes obstruction of bronchi with secondary suppurative disease emphysema, or atelectasis distally Expansion of the chest wall is usually greatly restricted on the involved side Progress is rapidly downward

X-ray examination may show evidence of pleural thickening This may be especially well brought out by producing a slight pneumothorax following thoracentesis Increased resistance to insertion of the needle in performing a thoracentesis is suggestive evidence, but even with extremely thick tumor this may be absent Cytologic study of the sediment from thoracenteses or a plug from the aspirating needle may establish the presence of malignancy yet only by exploratory thoracotomy can an absolute diagnosis be established

Treatment is largely symptomatic Repeated thoracenteses may be required for relief of dyspnea, but fluid almost invariably recurs with great rapidity All cases are fatal in from 6 to 9 months It is hoped that earlier recognition may permit extrapleural resection in some cases

## CHEST INJURIES

By J WINTHROP PEABODY M D and J WINTHROP PEABODY JR M D

Injuries of the thoracic wall the lungs and the heart if not soon fatal remain of concern however slight they may seem because of the complications that may develop Injuries of the chest are of two types—penetrating and nonpenetrating—both equally serious Even without outward evidence of injury the ribs may be broken and lacerate the lung the diaphragm may be ruptured allowing the abdominal organs or blood from an injured liver to enter the pleural cavity or the injured thoracic wall may have torn the blood vessels and caused a hemothorax Blast injury results from sudden increased intrathoracic pressure caused by detonation of explosives

Injury to the thoracic wall or the lung produces a painful cough which the patient may try to repress with the result that the respiratory passages cannot free themselves from blood or other secretions and atelectasis may develop

*Clinical Features* —Patients with thoracic injuries should be hospitalized at once because of possible concealed injuries or complications The patient on examination is apprehensive and has a dry irritating cough perhaps with bloody sputum and the sides of his chest move unequally The alterations in the blood pressure respiration and pulse rates are indicative of shock If there is a gaping hole in the chest a sucking sound as of air being drawn inward can be heard and there may be a gurgling sound The thorax may be distended with air the mediastinum displaced toward the uninjured side A normal vesicular murmur on auscultation indicates air is entering the lung and increased intrapleural pressure is indicated by displacement of the apex beat and trachea A pleural or pericardial friction rub may later be heard A developing emphysema will produce a resonant sound on percussion or crackling sounds on auscultation Paradoxical breathing denotes a stove in chest and demands immediate surgical attention

Roentgenologic examination should be delayed until after emergency treatment if the patient s condition is serious unless perforation of the bowel is suspected The underlying viscera may be injured with or without fracture of the ribs Fracture of the ribs will be indicated by pain at the site of fracture limited expansion of the chest on the affected side difficult breathing and palpable bone crepitus

*Treatment* —Treatment is of three general types immediate therapy to prevent death careful watching for and treatment of complications and surgical repair of structural defects Immediate therapy includes control of hemorrhage treatment of shock and bringing the cardiorespiratory mechanism back to normal as soon as possible Blood transfusion and oxygen therapy should be administered at once in cases of severe injuries of the chest Antibiotics should be given freely parenterally or orally in all cases of obviously or potentially infected injuries

## INHALATIONAL THERAPY

By ALVAN L BARACH M D

Although the physiological aspects of disturbances in respiration and circulation have been extensively studied, the practical application of these findings by appropriate physiologically directed treatment is more limited than our present knowledge would generally permit In fact relatively scant consideration has been accorded to the therapeutic use of gases and allied procedures in current text books on diseases of the lung and the heart despite increased admission that no emergency is more critical in clinical medicine than an interruption in the life-line of oxygen to the tissues

Respiration includes a two fold function

(1) External respiration concerned with the transmission of oxygen from the air to the arterial blood and the elimination of carbon dioxide from venous blood to the outer atmosphere the lungs and the respiratory passageway are primarily involved in this process

(2) Internal respiration concerned with the exchange of oxygen and carbon dioxide between the tissues and the blood the circulation the red corpuscles and hemoglobin and various enzymes concerned with oxidation are important links in internal respiration

The purpose of inhalational therapy may be described as an attempt to maintain or restore normal function in clinical disorders of external respiration Methods of treatment which developed from an understanding of the pathophysiology of these clinical entities are used to counteract functional or reversible pathology in the lungs and bronchi Although impairment of respiratory function ultimately manifests itself in a state of tissue oxygen want which may, at times be effectively treated by simple inhalation of an oxygen-enriched atmosphere, the recognition of more complex functional alterations in the respiratory system has stimulated the use of other gases as well as various types of pressure used either in conjunction with a therapeutic gas or with atmospheric air

### THE THERAPEUTIC USE OF OXYGEN

*Physiologic Aspects* —The central nervous system is most sensitive to damage by anoxia In recent years, the gradient of reaction in different parts of the brain has received special study The pathologic changes produced by anoxia may be initiated by various experimental methods, such as inhalation of low-oxygen mixtures carbon monoxide poisoning, and exposure to low barometric pressures In each instance a selective vulnerability of the brain has been described in the following order (1) the smaller pyramidal cells of the cortex (2) the Purkinje cells (3) the medulla retina and spinal cord and (4) the spinal root ganglions In these studies, the frontal lobe cortex was found to show pathological changes at times when the rest of the brain cortex was normal suggesting that the more recently developed elements in the central nervous system are more sensitive to injury perhaps because they require a higher oxygen consumption Cerebral anoxia has also been induced by increasing the oxygen up-take of the brain beyond the capacity of the existing oxygen supply as well as by decreasing the oxygen supply below the existing demand These and other findings in organic pathology of the brain as a result of anoxia have been correlated with functional disturbances created by inhaling low-oxygen atmospheres or by exposure to high altitudes Among the earliest symptoms of oxygen deficiency, produced by breathing 13 to 15 per cent oxygen or air at an altitude of 12,000 to 14,000 feet is impairment in emotional control, reason judgment and vision Other organs which are especially sensitive to anoxia include the heart the adrenal glands the kidneys and the lungs themselves

The degree of oxygen deficiency which takes place in clinical illness may be determined in certain instances by measuring the tension or saturation of the arterial blood

with oxygen The amount of oxygen which can be taken up by the hemoglobin and the plasma is primarily dependent upon the partial pressure of oxygen to which the blood is exposed The partial pressure of oxygen in the atmosphere is calculated by multiplying the percentage of oxygen by the barometric pressure after the pressure of water vapor has been subtracted At sea level 760 mm (the barometric pressure) minus 47 mm (pressure of water vapor) multiplied by 20 9 per cent, equals 150 mm or the partial pressure of oxygen in the atmosphere When either the barometric pressure or the concentration of oxygen is reduced the partial pressure of oxygen is lowered as follows

1 Reduced barometric pressure (360—47) × 20 9% = 65 4 mm
2 Reduced oxygen percentage (760—47) × 10% = 71 3 mm

In the first case, the partial pressure of oxygen in the atmosphere and in the alveolar air is lowered as a result of exposure to high altitude In the second instance of anoxia the partial pressure of oxygen in the arterial blood and in the alveolar air is decreased because of pathological changes either in the alveolar membrane and pulmonary capillaries as in pneumonia or congestive heart failure through accumulation of serous exudate in the alveoli as in edema of the lungs or because of inadequate and irregular ventilation of the air spaces as in pulmonary emphysema In the last case a lowered tension of oxygen in certain alveoli contributes unrespired blood to the aorta A decreased volume of breathing which occurs in respiratory paralysis due to poliomyelitis and excessive doses of sedative drugs likewise is followed by a lowered alveolar and arterial oxygen pressure

Under circumstances above mentioned a variable amount of reduced hemoglobin travels through the lungs without being adequately oxygenated which results in the characteristic bluish color known clinically as cyanosis However in patients who are anemic a low hemoglobin content may prevent the appearance of cyanosis even in the presence of severe arterial anoxia Furthermore the capillaries of the skin may be contracted as in shock in which case the bluish color may not be visible even in the presence of severe tissue oxygen want The concentration of carbon dioxide in the capillaries is also a factor which determines the presence or absence of visible cyanosis In conditions in which hyperventilation takes place a decrease in peripheral circulation is associated with an undue elimination of carbon dioxide

*Clinical Considerations* —Cyanosis is no longer relied upon as an indication of a deficient supply of oxygen to the tissues since it is generally a late sign Clinical judgment is necessary to appraise the degree of anoxia present especially such manifestations of impaired respiratory function as increased pulse rate irrationality dyspnea depressed breathing a grayish color to the face restlessness or irritability

In cardiac insufficiency the arterial blood may reveal only a slight decrease in saturation with oxygen, depending upon the degree of pulmonary congestion at a time when severe tissue oxygen lack is present The measurement of the oxygen saturation of mixed venous blood would be required in order to determine the degree of anoxia due to retarded circulation a procedure carried our in the Fick measurement of cardiac output in patients who receive special study Anoxia is a result of anemia may be diagnosed from analysis of the mixed venous blood, or estimated by the hemoglobin content

Serious local tissue anoxia may take place as a result of thrombosis of the coronary cerebral or other arteries without significant alteration of the arterial or mixed venous oxygen tension Nevertheless the administration of oxygen may be of crucial importance in these conditions because of the increase in the partial pressure of oxygen in the plasma of the collateral or partially occluded blood vessels even though no precise measurement of tissue anoxia can be obtained under these circumstances

Oxygen want produced by exposure to poisons which interfere with the oxidation mechanism in the cell is another kind of anoxia difficult to estimate In this class are included such histotoxic agents as cyanide and alcohol Cyanide produces its effect by inactivating the iron-containing oxygen car

## INHALATIONAL THERAPY

By ALVAN L BARACH M D

Although the physiological aspects of disturbances in respiration and circulation have been extensively studied, the practical application of these findings by appropriate physiologically directed treatment is more limited than our present knowledge would generally permit In fact relatively scant consideration has been accorded to the therapeutic use of gases and allied procedures in current text books on diseases of the lung and the heart despite increased admission that no emergency is more critical in clinical medicine than an interruption in the life-line of oxygen to the tissues

Respiration includes a two fold function

(1) External respiration concerned with the transmission of oxygen from the air to the arterial blood and the elimination of carbon dioxide from venous blood to the outer atmosphere the lungs and the respiratory passageway are primarily involved in this process

(2) Internal respiration concerned with the exchange of oxygen and carbon dioxide between the tissues and the blood the circulation the red corpuscles and hemoglobin, and various enzymes concerned with oxidation are important links in internal respiration

The purpose of inhalational therapy may be described as an attempt to maintain or restore normal function in clinical disorders of external respiration Methods of treatment which developed from an understanding of the pathophysiology of these clinical entities are used to counteract functional or reversible pathology in the lungs and bronchi Although impairment of respiratory function ultimately manifests itself in a state of tissue oxygen want which may at times be effectively treated by simple inhalation of an oxygen-enriched atmosphere the recognition of more complex functional alterations in the respiratory system has stimulated the use of other gases as well as various types of pressure, used either in conjunction with a therapeutic gas or with atmospheric air

### THE THERAPEUTIC USE OF OXYGEN

*Physiologic Aspects* —The central nervous system is most sensitive to damage by anoxia In recent years the gradient of reaction in different parts of the brain has received special study The pathologic changes produced by anoxia may be initiated by various experimental methods such as inhalation of low-oxygen mixtures carbon monoxide poisoning and exposure to low barometric pressures In each instance a selective vulnerability of the brain has been described in the following order (1) the smaller pyramidal cells of the cortex (2) the Purkinje cells (3) the medulla, retina and spinal cord, and (4) the spinal root ganglions In these studies, the frontal lobe cortex was found to show pathological changes at times when the rest of the brain cortex was normal, suggesting that the more recently developed elements in the central nervous system are more sensitive to injury, perhaps because they require a higher oxygen consumption Cerebral anoxia has also been induced by increasing the oxygen up-take of the brain beyond the capacity of the existing oxygen supply as well as by decreasing the oxygen supply below the existing demand These and other findings in organic pathology of the brain as a result of anoxia have been correlated with functional disturbances created by inhaling low-oxygen atmospheres or by exposure to high altitudes Among the earliest symptoms of oxygen deficiency, produced by breathing 13 to 15 per cent oxygen or air at an altitude of 12 000 to 14 000 feet is impairment in emotional control reason judgment and vision Other organs which are especially sensitive to anoxia include the heart the adrenal glands, the kidneys, and the lungs themselves

The degree of oxygen deficiency which takes place in clinical illness may be determined in certain instances by measuring the tension or saturation of the arterial blood

precipitated by respiratory infection the opportunity of a gradual program of oxygen administration is not available However an understanding of the possibility of respiratory acidosis should be kept in mind and oxygen administered in as low concentrations as are consistent with the safety of the patient in respect to the menace of anoxia The treatment for respiratory acidosis is difficult Intravenous sodium lactate has been employed by the author with evidence of clinical improvement Increasing the ventilation of the patient by a mechanical resuscitating device will also be of help

In patients with congestive heart failure either due to acute or chronic cardiac insufficiency relief of dyspnea is not accompanied by respiratory acidosis of any significant degree The pulmonary ventilation is lowered but the rise in $CO_2$ tension is apt to take place in a more gradual manner allowing the compensatory mechanisms to come into play before respiratory acidosis of significant degree manifests itself Carbon dioxide diffuses into the expired air more readily in passive pulmonary congestion than in either organic or functional pulmonary emphysema due to severe asthma in which many alveoli are poorly ventilated

The use of oxygen in patients with depressed respiration such as respiratory paralysis occurring in poliomyelitis should be controlled if possible by a determination of the arterial or alveolar $CO_2$ tension and the pH of either arterial or venous blood Although oxygen is frequently indicated in respiratory paralysis the degree to which the ventilation may be decreased is not easily measured Some form of mechanical breathing such as the tank respirator is indicated under circumstances in which oxygen relieves anoxia but not elimination of carbon dioxide Similarly in conditions in which the respiration may be depressed by drugs oxygen is best given in conjunction with devices which maintain an adequate pulmonary ventilation

In patients with obstructive dyspnea such as bronchial asthma with an associated functional over inflation of the lungs increase in carbon dioxide content with respiratory acidosis may occasionally take place and deserves appropriate treatment as outlined above In most instances however the proprioceptive reflexes in patients with asthma are sufficiently stimulated to maintain an adequate volume of ventilation which prevents respiratory acidosis unless excessive doses of barbiturate drugs have been employed In the treatment of local ischemic anoxia respiratory acidosis is not a factor Relatively high concentrations of oxygen from 60 to 70 per cent are frequently indicated continuously in such acute anoxic states as coronary thrombosis and cerebral thrombosis

Although oxygen in high concentrations may be given by mask for short periods of time the discomfort generally produced by continuous application of a mask renders it a less suitable agent than either the nasal catheter or the oxygen tent The maintenance of a concentration of 50 to 60 per cent oxygen by a flow of 12 liters to 15 liters per minute is now generally possible with the mechanically air-conditioned tent Undue accumulation of carbon dioxide will necessarily take place in any tent in which a flow of oxygen of less than 10 liters a minute is administered Even low concentrations of carbon dioxide in a tent tend to provoke increasing dyspnea in patients with pulmonary and cardiac disease The Meter mask has the advantage of not permitting re breathing and is generally to be preferred to the BLB apparatus in which concentrations of carbon dioxide of 2 per cent are frequently present during the administration of moderate flows of oxygen such as 4 to 5 liters per minute Furthermore the resistance in the sponge rubber discs of the BLB mask results in increased inspiratory effort when the valves function by admitting air from the outside atmosphere The fact that a prescribed concentration of oxygen from 40 to 100 per cent can be accurately administered with the injector of the Meter mask is an additional reason for employing this apparatus in routine oxygen therapy A description of the proper methods of carrying out the various procedures of inhalational therapy is beyond the province of this chapter they have recently been emphasized in the publication of the Standards of Effective Administration of Inhalational Therapy by the Committee on Public Health Rela

rier of the tissue cell which is a hematin compound cytochrome distinct from hemoglobin but related to it and capable of combining reversibly with oxygen Alcohol produces its effect by stabilizing oxycytochrome so that oxygen is not removed from the cell at the normal rate Inhalation of high oxygen atmospheres may increase the proportion of total cytochrome in the oxygenated form and thereby counteract to some extent the diminution of catalytic efficiency which the cytochrome suffers in contact with alcohol

A program of oxygen treatment depends upon an estimation of the degree of either arterial stagnant or other anoxia present as well as the calculated response to oxygen therapy based on previous experience in the clinical entity being treated In the use of oxygen for the prevention or treatment of anoxia in lobar or broncho pneumonia, the inhalation of a 50 per cent oxygen-enriched atmosphere is usually employed, since restoration of the arterial saturation to or near the normal value is generally obtained by this increase in alveolar oxygen In more severe anoxia the oxygen concentration is increased to 60 or 70 per cent but the administration of 100 per cent oxygen is allowed for no longer than 12 hours since irritant effects are produced in the lungs by concentrations of 80 per cent or above when inhaled continuously for prolonged periods

Relief of anoxia in pneumonia is generally accompanied by disappearance of cyanosis if present, a slight or moderate decrease in respiratory rate or volume diminution of dyspnea and restlessness The carbon dioxide content of the arterial blood is not significantly altered unless widespread bilateral disease is present The patient is treated with continuous administration of oxygen until the pneumonic process in the lungs has cleared sufficiently to allow removal from the oxygen-enriched atmosphere without an increase in pulse rate of over 10 or 15 beats per minute and without recurrence of dyspnea In extensive involvement of both lungs, abrupt removal from an oxygen-enriched atmosphere may provoke sharp return of obvious impairment of respiratory function

When the clinical entity being treated with administration of 50 per cent oxygen belongs to the group of cases in which a marked decrease in pulmonary ventilation takes place a respiratory acidosis may ensue because of inadequate elimination of carbon dioxide The onset of this complication is especially apt to take place in patients with pulmonary emphysema who are given high concentrations of oxygen to relieve chronic anoxic dyspnea, or who are treated for acute anoxia because of an exacerbation of dyspnea due to intercurrent respiratory infection The decrease of the volume of breathing engineered by the effect of oxygen on the carotid sinus is followed by relief of dyspnea without, however, a prompt development of the compensatory elimination of chlorides and retention of base and an adequate mechanism for excreting carbon dioxide in a decreased volume of breathing Under these circumstances, an increase in arterial $CO_2$ tension takes place with a rapid shift in pH toward acidity Delirium and coma may result with other manifestations of acidosis Because of the presence of irregular ventilation of alveolar cells which in many cases are deficiently diffused with air even prior to oxygen administration accumulation of $CO_2$ takes place with great rapidity even though dyspnea has been relieved through inhalation of high concentrations of oxygen

In cases in which oxygen administration is contemplated for these patients with chronic anoxic dyspnea acidosis may be avoided by a program of gradually increasing the concentration of oxygen delivered to the patient such as the use of the nasal catheter with a flow of one liter of oxygen per minute on the first day of administration increasing the flow every two to three days by one liter a minute until the desired rate 6 or 7 liters per minute is obtained At this time the treatment may be continued in a tent with 50 per cent oxygen without respiratory acidosis or mental changes of an adverse nature taking place even though the $CO_2$ content and tension of arterial blood have become elevated markedly above normal Compensation to the increased $CO_2$ tension in the blood is gradually developed by retention of base and elimination of chlorides from the urine In cases in which acute anoxia has been

precipitated by respiratory infection the opportunity of a gradual program of oxygen administration is not available However an understanding of the possibility of respiratory acidosis should be kept in mind and oxygen administered in as low concentrations as are consistent with the safety of the patient in respect to the menace of anoxia The treatment for respiratory acidosis is difficult Intravenous sodium lactate has been employed by the author with evidence of clinical improvement Increasing the ventilation of the patient by a mechanical resuscitating device will also be of help

In patients with congestive heart failure either due to acute or chronic cardiac insufficiency relief of dyspnea is not accompanied by respiratory acidosis of any significant degree The pulmonary ventilation is lowered but the rise in CO tension is apt to take place in a more gradual manner allowing the compensatory mechanisms to come into play before respiratory acidosis of significant degree manifests itself Carbon dioxide diffuses into the expired air more readily in passive pulmonary congestion than in either organic or functional pulmonary emphysema due to severe asthma in which many alveoli are poorly ventilated

The use of oxygen in patients with depressed respiration such as respiratory paralysis occurring in poliomyelitis should be controlled if possible by a determination of the arterial or alveolar CO tension and the pH of either arterial or venous blood Although oxygen is frequently indicated in respiratory paralysis the degree to which the ventilation may be decreased is not easily measured Some form of mechanical breathing such as the tank respirator is indicated under circumstances in which oxygen relieves anoxia but not elimination of carbon dioxide Similarly in conditions in which the respiration may be depressed by drugs oxygen is best given in conjunction with devices which maintain an adequate pulmonary ventilation

In patients with obstructive dyspnea such as bronchial asthma with an associated functional over inflation of the lungs increase in carbon dioxide content with respiratory acidosis may occasionally take place and deserves appropriate treatment as outlined above In most instances however the proprioceptive reflexes in patients with asthma are sufficiently stimulated to maintain an adequate volume of ventilation which prevents respiratory acidosis unless excessive doses of barbiturate drugs have been employed In the treatment of local ischemic anoxia respiratory acidosis is not a factor Relatively high concentrations of oxygen from 60 to 70 per cent are frequently indicated continuously in such acute anoxic states as coronary thrombosis and cerebral thrombosis

Although oxygen in high concentrations may be given by mask for short periods of time the discomfort generally produced by continuous application of a mask renders it a less suitable agent than either the nasal catheter or the oxygen tent The maintenance of a concentration of 50 to 60 per cent oxygen by a flow of 12 liters to 15 liters per minute is now generally possible with the mechanically air conditioned tent Undue accumulation of carbon dioxide will necessarily take place in any tent in which a flow of oxygen of less than 10 liters a minute is administered Even low concentrations of carbon dioxide in a tent tend to provoke increasing dyspnea in patients with pulmonary and cardiac disease The Meter mask has the advantage of not permitting re breathing and is generally to be preferred to the BLB apparatus in which concentrations of carbon dioxide of 2 per cent are frequently present during the administration of moderate flows of oxygen such as 4 to 5 liters per minute Furthermore the resistance in the sponge rubber discs of the BLB mask results in increased inspiratory effort when the valves function by admitting air from the outside atmosphere The fact that a prescribed concentration of oxygen from 40 to 100 per cent can be accurately administered with the injector of the Meter mask is an additional reason for employing this apparatus in routine oxygen therapy A description of the proper methods of carrying out the various procedures of inhalational therapy is beyond the province of this chapter they have recently been emphasized in the publication of the Standards of Effective Administration of Inhalational Therapy by the Committee on Public Health Rela-

tions of the New York Academy of Medicine, and are given in detail in the author's textbook

When oxygen is administered for the purpose of restoring compensation in chronic pulmonary or cardiac disease, the termination of treatment is carried out by gradual decrease in the concentration of oxygen in the atmosphere The decrease in hemoglobin and red blood cell count that takes place as a result of oxygen treatment over long periods of time is one of the mechanisms which should be counteracted in reverse by a gradual exposure of the patient to an oxygen atmosphere that approaches that of air

### The Therapeutic Use of Carbon Dioxide

When it became apparent that carbon dioxide regulated respiration in a precise way the ventilation increasing with the increased concentration of $CO_2$ in the alveolar air the use of carbon dioxide as a therapeutic agent was developed primarily in order to produce an augmentation of breathing At one time it was thought that carbon dioxide was lost from the blood at times as a result of dyspnea in a variety of clinical entities with the result that a condition of alkalosis took place but this reaction now appears to be rare indeed When respiratory alkalosis does take place, engendered by hyperventilation the hemoglobin is bound more tightly to oxygen and the tissues are exposed to a low oxygen tension even though the hemoglobin itself may have an increased oxygen concentration When an unduly increased volume of breathing occurs as a response to anoxia as at high altitude, the remedy for the situation is plainly that of providing an increased oxygen atmosphere and not carbon dioxide

In clinical illness, the use of carbon dioxide has been largely abandoned since the evidence on which its employment was based has not been supported by more careful studies which have revealed respiratory acidosis with elevated arterial carbon dioxide tension in conditions such as sedative and narcotic poisoning atelectasis of the lungs of the newborn and other kinds of respiratory failure Even in the treatment of carbon monoxide poisoning in which the inhalation of 5 to 7 per cent $CO_2$ with oxygen displaces CO from hemoglobin the superiority of carbon dioxide in oxygen over inhalation of pure oxygen alone has been seriously questioned

In any form of obstructive dyspnea a carbon *dioxide concentration* above 1 per cent or more results not only in increased ventilation but in an increase in the negative pressure within the chest necessary to pull air into the lungs with the result that an increased tendency for exudation of serum and mucus in the respiratory passageway takes place When an increase in the volume of breathing is required the use of oxygen enriched atmospheres combined with some form of mechanical ventilation is generally indicated rather than carbon dioxide, which would increase the respiratory acidosis generally present In postoperative conditions deep breathing is no longer carried out by inhalation of high $CO_2$ concentrations as in some instances carbon dioxide acidosis is already present Turning the patient on the side or ventilating the patient after operation by intermittent pressure on the anesthesia bag is preferable

The use of 5 to 10 or, at times 15 per cent carbon dioxide in the treatment of intractable hiccup constitutes its main value at the present time When carbon dioxide is administered until the patient almost loses consciousness 2 to 3 minutes for 10 per cent $CO_2$ and 1½ minutes for 15 per cent $CO_2$ the hiccup may be relieved The procedure is often repeated at 3 hour intervals with marked clinical benefit The inhalation of high concentrations of carbon dioxide between 15 and 30 per cent has been used in the treatment of psychosis Dyspnea disorientation and a rise in systolic blood pressure takes place before onset of unconsciousness which is the goal of treatment in clinical entities such as dementia praecox and certain psycho-neuroses

### The Therapeutic Use of Helium

Helium was introduced as a therapeutic gas in 1934 for the treatment of intractable bronchial asthma and obstructive dyspnea

due to constricted lesions in the respiratory passageway. When helium is substituted for nitrogen a uniform mixture of the two gases takes place which then has the property of a single gas one third lighter than air.

The lighter the gas the more rapidly it diffuses, the formula being: the rate of diffusion of a gas is inversely proportional to the density of the gas (Graham's law). When a mixture of 80 per cent helium and 20 per cent oxygen is in the alveoli the increased rate of diffusion in comparison to air is as 1.7 to 1. The physical advantage of more rapid diffusion of a helium-oxygen mixture is observed in atelectasis of the lungs, obstruction of the Eustachian tube produced either by rapid descent in an airplane or too swift ascent to air at atmospheric pressure after previous exposure to increased pressures in tunnels. Similarly the passage of a gas through a constricted orifice varies inversely with the square root of the molecular weight of the gas or gas mixture. Thus a regulator attached to an oxygen cylinder at a flow of 1 liter per minute will deliver a velocity flow of 1.7 liters when attached to an 80 per cent helium—20 per cent oxygen cylinder.

In studies carried out by subjecting a spirometer to mechanical movement and having it breathe various gases through fixed orifices, either the velocity of movement of the helium-oxygen mixture could be increased at a constant pressure or the pressure lowered to effect a constant velocity of gas movement. The advantage of inhaling the helium-oxygen mixture is increased in proportion to the extent to which the constriction is localized, which results in turbulence, and decreased if the narrowing is prolonged in a linear direction, since the viscosity of helium is greater than that of nitrogen.

In obstructive dyspnea the effect of the helium-oxygen mixture makes possible a shorter period of inspiration with the consequence that a more normal volume flow of respiration is achieved with less effort. This finding has been confirmed by measuring the decrease in intrapleural negative pressure during inspiration in a patient with severe bronchial asthma and in experimental tracheal obstruction in dogs.

In bronchial asthma intermittent inhalations of an 80 per cent helium—20 per cent oxygen mixture are given to relieve severe dyspnea and in addition to provide a cumulative effect of bronchial relaxation which is produced by the physical influence of decreased respiratory effort. In constricting lesions of the respiratory passageway helium-oxygen mixtures have been given continuously at times with the result that tracheotomy for laryngeal dyspnea has been averted. Better alveolar ventilation as a result of inhalation of helium-oxygen mixtures has been responsible for its use in unresolved pneumonia, atelectasis of the lungs in adults and in the newborn infant.

The most feasible method of administration is the use of the Meter mask with an expiratory pressure of 2 to 3 cm. of water. The strict avoidance of rebreathing masks in the treatment of any type of bronchial obstruction is necessary since there already is increased carbon dioxide retention in this condition. The increased expiratory pressure maintains a wider lumen of the smaller bronchi during expiration and facilitates elimination of the inspired atmosphere with the use of increased contraction of the abdominal and lower intercostal muscles. The relief of obstructive dyspnea is enhanced when pressure breathing in inspiration and expiration is provided, as discussed in the following section.

## The Therapeutic Use of Pressure Breathing

A variety of clinical disturbances in respiration and circulation are treated with pressure breathing either in conjunction with administration of therapeutic gas mixture or with air itself. The indications and physiological effects of application of pressure in inhalational therapy will be considered under the following subdivisions: (1) continuous pressure breathing, (2) expiratory pressure breathing, (3) intermittent inspiratory pressure breathing, (4) equalizing pressure respiration with or without constant lung volume and with or without mechanically induced coughing.

### Continuous Pressure Breathing

Continuous pressure breathing refers to the application of a relatively constant pressure above the atmosphere approximately equal during inspiration and expiration during the inhalation of air or a therapeutic gas mixture. Its main uses are in the treatment of asthma, constrictive lesions in the larynx or trachea and pulmonary edema. In obstructive dyspnea the negative intrapleural and intra pulmonary pressure becomes pathologically elevated during inspiration mirroring the increased effort required to inhale air past the point of constriction in the respiratory passageway. The inhalation of an atmosphere under increased pressure results in decreased inspiratory effort, which is revealed by an immediate lowering of the intrapleural negative pressure during the inspiratory cycle. The maintenance of a similar pressure during expiration results in an increased volume of air in the lungs and widening of the lumen of the bronchi and bronchioles, thus diminishing constriction of the respiratory tract in respiration.

The return of blood to the right heart is retarded depending upon the mean pressure applied to the lungs. The venous pressure is elevated in normal subjects about 40 per cent of the applied intrapulmonary pressure, the remaining 60 per cent of the mean pressure used is absorbed by the lungs, chest wall and diaphragm, which at the end of inspiration constitutes the relaxation pressure of the chest that accomplishes expiration. In patients with pulmonary congestion due to heart failure the rise in venous pressure may be 60 to 70 per cent of the applied pressure, reflecting the diminished elasticity of the lungs under these circumstances. In patients with cardiac insufficiency damming back of blood into the peripheral circulation is an advantage since it allows the heart to cope with a smaller volume of blood. This is of special importance in the treatment of pulmonary edema; in addition an increased intrapulmonary pressure is exerted on the pulmonary capillaries only part of which is compensated for by an increase in right auricular and pulmonary capillary pressure. It would seem likely that the pulmonary capillaries are relatively compressed under these circumstances, thus decreasing the tendency of serum to leak outward.

Continuous pressure breathing should be administered cautiously in shock since the impairment in cardiac output may be made worse by interfering with venous return. If an urgent indication for pressure breathing exists, such as pulmonary edema, small increases of pressure such as 2 to 3 cm of water may be given if plasma or blood is administered at the same time. The blood pressure should be followed at 15 minute intervals in patients with peripheral circulatory failure and pressure employed should be reduced or discontinued if a fall greater than 10 mm Hg takes place in the systolic pressure during application of pressure breathing.

Pressure breathing is used in aviation medicine at high altitudes in which pure oxygen is inhaled in order to increase the partial pressure of oxygen dissolved in the plasma. A decrease of cardiac output of 20 per cent has been found in normal individuals who breathe pressures of 20 cm of water or above. However, in clinical practice a continuous pressure in the mask (or hood) of 4 to 6 cm is generally adequate for the treatment of obstructive dyspnea and edema of the lungs. When the condition of the patient is improved the pressure is very gradually reduced, 1 cm every two to three hours, in order to prevent a sudden inlet of blood into the right heart or perhaps return of dyspnea or edema. When pressures of 6 cm are employed the circulation time is prolonged especially in circulatory failure and the record of the ballistograph shows definite although slight decrease in cardiac impact. Pressure breathing is used in conjunction with 40 to 50 per cent oxygen or with 20 to 30 per cent oxygen with the diluent gas helium, the latter being especially helpful in asthma and in constrictive lesion of the larynx and trachea.

The methods employed include a positive pressure hood and a mask apparatus that makes use of weights on two rubber bags into which the therapeutic gas mixture is admitted. When a distensible rubber bag is available continuous pressure breathing

may be simply obtained not only in expiration but in inspiration also as a result of the elastic recoil of the collecting bag

### Expiratory Pressure Breathing

Expiratory positive pressure breathing permits inspiration at atmospheric pressure with expiration against a resistance which increases the intrapulmonary pressure only during the expiratory cycle. The use of this device is primarily for the treatment of edema of the lungs and for the administration of helium-oxygen mixtures in patients with bronchial asthma. Expiratory positive pressure is also employed after tracheotomy to combat the increase in seromucoid exudate that follows relief of laryngeal obstruction. Since pressure is not present during inspiration the effect on cardiac output is much less marked than in continuous pressure breathing although retardation of blood flow into the right heart takes place during the expiratory cycle with pressures of 4 to 5 cm of water.

The Meter mask is used with a metal disk which surrounds the expiratory flutter valve and contains on its external surface five orifices of different diameters. With the largest opening expiration proceeds without pressure; as the disk is turned to the smaller orifices the patient exhaled under an increased pressure of 1 to 4 cm of water or more depending upon the volume of breathing. A more accurate control of pressure may be obtained if the exhaled air is conducted through a water bottle calibrated in centimeters of water. The expiratory pressure Meter mask apparatus is the most convenient of the methods in use for the treatment of edema of the lungs either due to pneumonia left ventricular failure shock or irritant gas poisoning. Pressures of 4 to 5 cm of water are first employed and then gradually lowered when the signs of serous exudate in the lungs have disappeared. The rubber collecting bag is kept distended by administration through the injector attached to the regulator of 40 to 50 per cent oxygen at a flow of 12 to 15 liters per minute

### Intermittent Inspiratory Pressure Breathing

Intermittent inspiratory positive pressure consists of the administration of pressure which automatically inflates the lungs during inspiration expiration occurring either as a result of the relaxation pressure of the lungs and chest wall or mechanically by means of a negative pressure induced during the expiratory cycle; respirators of the latter type are known as suck and blow resuscitators. These apparatuses are used for respiratory failure due to a depressed or inadequate respiratory stimulus as in such conditions as poisoning with barbiturates morphine carbon monoxide alcohol as well as in drowning certain types of coma poliomyelitis with respiratory paralysis and electrocution.

When artificial respiration is employed especially with stuporous or unconscious subjects special attention must be given to clearing the respiratory passageway of mucus or other foreign matter by appropriate suction. The tongue is kept well forward and the head and neck maintained in extension with the chin somewhat elevated. When bronchospasm or pulmonary edema is present the inhalation of nebulized bronchodilator and broncho-vasoconstrictor drugs during the administration of intermittent pressure breathing may be found useful.

The effect of intermittent pressure breathing on the circulation is dependent upon the mean pressure employed. With apparatus in which the lungs are inflated by a positive pressure of 10 to 14 mm Hg with the pressure falling gradually to the atmosphere as a result of elastic recoil of the lungs and chest wall the mean pressure varies from 3 to 6 mm Hg depending upon the shape of the pressure curve. Interference with cardiac output may then take place under the circumstances previously described.

A similar effect on the circulation is produced by the tank type of respirator in which a negative pressure is created within the chamber achieving a gradient of pressure from the atmosphere into the lungs similar to that maintained by inspiratory positive pressure applied with a mask. In each instance the rise in venous pressure has been

found to be similar provided the mean pressure is the same When intermittent pressure breathing is used by an apparatus which provides a swift expiration and a long expiratory pause, the mean pressure is smaller and hence the effect on venous pressure and cardiac output is less Intermittent inspiratory pressure breathing is useful in the treatment of pulmonary edema in unconscious subjects but it is not generally helpful for the dyspnea of conscious patients who often require a higher velocity of air flow during inspiration than is provided by respirators now available In patients in whom peripheral circulatory failure is present the use of the positive and negative pressure (suck and blow) respirator appears to be preferable because they are effective and safe to use with unconscious subjects and the mean average pressure being near zero, produces no retardation of venous return and no impairment of cardiac output There is no convincing evidence that these forms of apparatus have deleterious effects on the lungs In all types of artificial respiration apparatus rapid tripping indicates that oxygen or air is not reaching the alveoli because of some obstruction

In respiratory paralysis the tank respirator may be used with a negative pressure of minus 15 to minus 20 cm of water and with a positive pressure within the tank of plus 5 to plus 8 cm instead of the entire pressure being employed on the negative side The effective mean positive pressure gradient would then be lower which would be of value in patients with circulatory failure High negative pressures within the tank being similar to high inspiratory positive pressure applied with a mask effective ventilation may be in some cases aided by adding an increase in intra tank positive pressure In this way anoxia and respiratory acidosis may be prevented without an undue blockage of venous return In current studies a swiftly opening valve has been attached to the tank respirator in which the pressure drop from minus 45 cm of water within the tank to the atmosphere takes place in 0 06 seconds, which results in a low mean pressure and has been shown to facilitate the elimination of bronchial secretions by increasing the velocity of air leaving the lungs during expiration, as a result of the relaxation pressure of the chest being exerted without hindrance from a gradually decreasing negative tank pressure

## Equalizing Pressure Respiration With or Without Constant Lung Volume and With or Without Mechanically Induced Coughing

Pressure respiration with a constant lung volume is provided by a chamber in which the patient is completely enclosed and exposed to a swift variation in air density by which an adequate pulmonary ventilation is achieved without necessity for voluntary respiration or chest movement An alternating pressure of 100 mm Hg thirty times a minute is provided by air entering and leaving the head end of the chamber from a motor blower or compressor unit A collar that partially surrounds the neck of the patient functions as a baffle reducing and delaying the air pressure wave to the outer chest wall to the same degree that the tracheobronchial tree exercises a resistance to air entering the alveoli and hence the inner surface of the thorax Similarly the wave of positive and negative pressure is exerted simultaneously and with equal force on the upper and lower surfaces of the diaphragm

Although patients may breathe freely in a chamber of this kind because there is no gradient of pressure difference between the inner surface of the lungs and the prevailing atmospheric pressure the chamber has been made use of for the treatment of pulmonary tuberculosis by training the patient to dispense with voluntary breathing and therefore with chest movement A normal pulmonary ventilation or an increased ventilation of the lungs may be continuously maintained by this method even in the presence of respiratory paralysis or a certain degree of obstruction in the respiratory passageway In recent studies the dyspnea of patients with bronchial asthma and pulmonary emphysema have been found to be promptly relieved a few seconds after equalizing pressure respiration has been accomplished Patients with orthopnea of moderate degree due to congestive heart failure have also

been able to lie supine without the sensation of shortness of breath

When patients suspend voluntary breathing a striking mental and physical relaxation takes place The output of potassium in the urine is diminished and the serum potassium is elevated during residence in the chamber which suggests that the adrenal gland is under less stimulation than normal The cardiac impact as measured by the Dock ballistocardiograph may be reduced 30 per cent below the level obtained at ordinary bed rest The pulse and blood pressure are lowered and the T wave in the electrocardiogram is slightly elevated The physiological effects noted point to a sharp decrease in oxygen consumption and general metabolic work incident to not only the diminished energy due to cessation of respiratory movement but largely to the mental and physical quiet which this form of ventilation without chest movement induces

In current investigations the chamber is being employed in patients with respiratory paralysis The ability to breathe at will without the imposition of the negative pressure in the tank respirator may prove to be helpful to patients with bulbar poliomyelitis both during the acute stage of the disease and later when attempts are made to accustom the patient to breathe without the respirator

A modification of this chamber has been made in which a mechanically induced cough is provided The head end of the chamber is connected to a valve which opens at the peak of the positive pressure cycle in 0 012 seconds which results in a high velocity of air leaving the lungs At the same time the baffle is closed tightly around the neck to produce a differential pressure of 40 mm Hg on the abdomen and chest wall In this way the human cough is simulated since the levator rib muscles hold the chest from expanding when the glottis is suddenly opened at the end of inspiration The momentary application of pressure to the abdomen is transmitted to the diaphragm this appears to be of crucial importance in eliminating mucus and purulent material in patients with bronchiectasis bronchial asthma and respiratory paralysis Preliminary clinical trials on human subjects and experiments on animals suggest that a mechanically induced cough may be of value in those clinical entities in which bronchial secretions are not gotten rid of because of impairment in the neuromuscular mechanism responsible for an effective human cough

## The Inhalation of Bronchodilator and Antibiotic Aerosols

Nebulization of bronchodilator and antibiotic drugs has been employed with the purpose of depositing these drugs in high concentration on the respiratory passageway and in the alveoli The site of deposition and absorption from the respiratory tract of therapeutic aerosols is dependent upon a number of factors especially the size of the droplets in the mist Particles of small size such as 0 3 to 0 8 micron in radius pass readily through the tracheobronchial tree to the alveoli where 60 to 70 per cent of them are absorbed depending upon the nature of the substance However particles of relatively large size such as 10 to 30 microns in radius are mostly precipitated on the pharynx larynx and trachea

In the treatment of bronchospasm it is preferable to employ a nebulin of bronchodilator solution of relatively small particle size such as 1 to 3 microns in radius in order to obtain both local application to the bronchioles and also absorption from the alveoli into the blood stream Solutions of 1 per cent epinephrine to 2 25 per cent racemic epinephrine are employed for quick relief of wheezing in patients with bronchial asthma and pulmonary emphysema Isopropyl adrenalin neosynephrin and at times atropine and sodium nitrate are also used in a nebulizer to produce vasoconstriction and bronchodilatation

In the treatment of bronchopulmonary infections with penicillin and other antibiotic aerosols deposition of the drug on the surface of the bronchial mucous membrane in a high local concentration is accomplished The sputum levels of penicillin when mists of a particle size between 1 and 3 microns in radius are inhaled are high in contrast to the absence of the drug when given intramuscularly Penicillin aerosol has been especially useful in the treatment of bronchiec

tasis in which more effective control of infection may be maintained by this method than by systemic administration. In inoperable advanced cases of bronchiectasis maintenance therapy of aerosol penicillin results in continued control of infection with, at times, remarkable relief of dyspnea and chronic infection. Penicillin resistant organisms are infrequently encountered with the exception of the hemolytic staphylococcus aureus but these resistant organisms may generally be eliminated by temporary marked increase in the dosage of penicillin aerosol.

In the treatment of acute and chronic in*fectious sinusitis aerosol penicillin has been* used in conjunction with the intermittent application of negative pressure to the nasal passages. In this way penicillin has been deposited in the accessory sinuses, at times with marked therapeutic benefit. The sulfonamide aerosols are also employed but have been largely superseded by penicillin and streptomycin. Streptomycin aerosol has been used in Friedländer B infections and in the treatment of bronchial and laryngeal tuberculosis in conjunction with parenteral administration of streptomycin. The newer antibiotic drugs terramycin aureomycin and chloromycetin do not lend themselves to aerosol administration because it is not as yet possible to give them in high enough concentration without irritation. However their administration by mouth or intravenously is especially valuable in overcoming infections with most resistant strains especially the Friedländer bacillus.

Penicillin aerosol has also been found to be of value in lung abscess and in chronic bronchitis refractory to intramuscular administration of the drug. Although originally used in the treatment of asthma and pulmonary emphysema in cases in which bronchial infection was present the incidence of increased bronchospasm is the physical result of the mist now makes it preferable to treat these conditions with systemic penicillin or with the newer antibiotic drugs.

Inhalation of penicillin and streptomycin in powdered form is less effective and more wasteful than by aerosol. Furthermore severe local reactions in the pharynx as well as serious bronchospasm in patients with asthma may be produced by penicillin administered as a dust. Although the inhalers available are convenient the clinical results are less good and the expense of continued use greater than effective administration of aerosol penicillin.

For the treatment of infections of the smaller bronchi a nebulizer is selected that produces particles of relatively small size such as 1 to 3 microns in radius, for the treatment of sinusitis a nebulizer that creates large-size particles is preferable in order to have a greater deposition on the nasopharyngeal mucous membrane and by use of *intermittent negative pressure* in the nasal accessory sinuses themselves. With adequate dosage and proper technique antibiotic aerosol therapy may result in marked benefit in the *clinical entities* for which aerosol therapy is intended such as bronchiectasis chronic bronchitis without bronchospasm sinusitis and lung abscess.

## ANTIMICROBIAL THERAPY

By H. Corwin Hinshaw, M.D.

The term *antimicrobial therapy* is receiving wide acceptance as a more inclusive and correct expression than *chemotherapy* or *antibiotic therapy*.

The most spectacular accomplishments in the field of antimicrobial therapy have been witnessed in the treatment of diseases of the respiratory tract.

*Therapeutic Objectives of Antimicrobial Therapy.*—The administration of specific drugs in infectious diseases of the respiratory tract is usually directed *toward retarding* the growth of the invading microbes, less frequently toward killing the microbes. Sometimes, as in pneumococcal pneumonia, inhibition for only a few days is sufficient to permit sufficient marshalling of the patient's defensive and reparative powers to lead to permanent healing. Sometimes, as in pulmonary tuberculosis, suppressive therapy must be continued for weeks or months before the disease can be arrested, and mechanical therapeutic aids are usually required. Sometimes, as in bronchiectasis, antimicrobial therapy is merely palliative and plays little part in effecting permanent arrest or cure of the disease. A logical approach to treatment would require the physician to define his therapeutic objective, guard against any possibility of unsatisfactory *progress toward it, and be prepared to modify* therapy as necessary.

It is unwise, however, to delay the treatment of fulminating disease until the bacteriologist verifies the physician's tentative etiologic diagnosis. *Frequently* the empirical use of penicillin has effected virtual cure before accurate bacteriologic and radiologic diagnosis has been achieved.

*The Pneumonias.*—*See* Chapter 5.

### Pulmonary Abscess

The therapeutic objective should be to treat each acute pulmonary infection with antibacterial agents adequately and before pulmonary abscess has developed. After necrotic processes have destroyed pulmonary parenchyma sufficiently to create an abscess cavity, the situation is so serious that prolonged illness and possible surgery are to be foreseen. However, a fair majority of pulmonary abscesses may be resolved by medical methods utilizing first penicillin and perhaps several antimicrobial agents in succession or in combination, if necessary, to control the infectious process. However

the factor of drainage is so important that antimicrobial therapy alone should not be depended upon without bronchoscopy, postural drainage, or, at times, surgical drainage Furthermore, it must be mentioned that bronchiogenic carcinoma, foreign bodies, bronchial strictures, bronchial adenomas, and rarer lesions may be the basis for any pulmonary abscess Interlobar empyema with bronchial fistula may simulate pulmonary abscess, and this was commonly seen before the day of virtually universal penicillin therapy in pneumonia

### Bronchiectasis

There is no definitive treatment for bronchiectasis except the radical surgical removal of all diseased pulmonary segments Before such operations the antimicrobial drugs are of great value in reducing the amount of purulent sputum and in improving the general condition of patients debilitated as a result of chronic pulmonary suppuration These drugs are of very great value in preventing the postoperative complications of empyema, postoperative atelectatic pneumonia and hematogenous dissemination of the infectious process (brain abscess, *etc* )

Inoperable bronchiectasis way offer insuperable obstacles which no amount or variety of drug therapy can surmount But dramatic results may be achieved by most intensive and prolonged efforts to control the *mixed bacterial infection largely responsible* for the distressing symptoms of the disease It is probable that the damaged bronchi never return to normal as a result of medical treatment but symptoms may be abated temporarily and when these recur as a result of reinfection, subsequent treatment may yield *similar results* However it is rarely observed that antimicrobial therapy can accomplish its goal without the most careful coordinated program of drainage and hygienic care

Penicillin and streptomycin have retained their popularity as the most practical agents in the treatment of bronchiectasis, and frequently the sulfonamides are worthy of trial Aureomycin, chloramphenicol and terramycin may be used for brief periods if well tolerated but these are seldom useful as the primary agents over prolonged periods

Penicillin and streptomycin may be administered by the aerosol method or by intramuscular injection or both The intramuscular method of injection offers some very *practical advantages, especially with* penicillin, but must be used with caution with *streptomycin because of the toxic* potentialities of the latter drug It is suggested that a trial period of intramuscular treatment with a mixture of penicillin (600,000 units daily) and streptomycin *(0 5 gm daily) be undertaken for a period of* approximately two weeks If hospitalization is feasible, it is well to utilize aerosol therapy simultaneously, but, if it is necessary for the patient to remain ambulatory aerosol treatment may be postponed until later

Aerosol therapy can never be administered *satisfactorily by means of the conventional* hand bulb as the source of motive power In hospitals an oxygen tank is most convenient and is always available It is equipped with a pressure-reducing valve and a flowmeter and is attached to a high-capacity glass nebulizer ( Vaponephrin ) with *a long length of rubber tubing It is more* economical to arrange a Y" connector to a by pass tube which will be closed with the patient s finger when he desires the nebulizer to operate during the inspiratory phase of respiration The nebulizer is charged by adding 1 cc of distilled water to the chamber, *and to this, a tablet of soluble crystalline* penicillin (50 000 units) is added and permitted to dissolve Streptomycin solution (100 to 200 mg in 0 5 cc water) may be added to counteract the Gram negative bacilli especially if these bacilli have been demonstrated on sputum smears The resultant solution may be nebulized and inhaled within 15 or 20 minutes It is suggested that this performance be repeated every one or two hours while the patient is awake Such intensive therapy is much more likely to be successful than a more leisurely program

It is advisable to save all sputum and note its character each day When the purulent component has disappeared the temporary goal has been achieved Frequent Gram stained smears of sputum will give an index

of the bacterial flora and it is especially important to do this if streptomycin is not being used When penicillin alone is used the Gram positive cocci frequently disappear promptly and are replaced by Gram negative bacilli of the coliform group The latter may disappear promptly when streptomycin therapy is added Sputum cultures are often less informative than simple smears of sputum stained by Gram s method

When the program described above has been adapted to the patient s needs and circumstances and given a good trial it may succeed in essentially sterilizing the tracheobronchial tree However such a happy state of affairs is not always realized When disappointment results it is well to try a course of treatment with aureomycin terramycin or chloramphenicol The dose tolerated readily will vary, but 0 5 gm four times daily is sufficient in some cases

Maintenance of a sterile tracheobronchial tree is of course an impossibility Maintenance doses of sulfonamide drugs (2 0 to 3 0 gm daily) may help to prevent or delay reinfection The usual cause of reinfection is an epidemic infection of the upper respiratory tract If penicillin is administered for a few days, reinfection may not occur

### Pulmonary Tuberculosis

In pulmonary tuberculosis antimicrobial therapy is most likely to be permanently effective against recently developed lesions lesions that have not progressed to necrosis The term *exudative tuberculosis* is frequently applied to lesions that have not yet caused marked lung changes and are therefore largely reversible Early tuberculous pneumonia and other types of extensive bronchiogenic or hematogenous pulmonary tuberculosis may be detected and treated effectively before coalescence of the numerous small foci has resulted in irreversible damage

Occasionally chronic indolent lesions of known long duration may retain a diffuse distribution and therefore be largely reversible but there is usually a close correlation between the age of a lesion and its reversibility However many large coalescent necrotic foci of pulmonary tuberculosis are surrounded by an extensive zone of disease which is capable of considerable resolution as a result of antibacterial drug therapy The central core of destroyed tissue will almost surely require collapse therapy or excision but resolution of the peripheral exudative component may be necessary to stem the progress of the disease and to permit effective mechanical treatment directed toward the central anatomical defect

It is difficult to determine the state of pathologic development of many lesions of pulmonary tuberculosis because the physician is so dependent upon radiographic methods of demonstration which are known to be fallible However experienced radiologists and physicians are becoming more adept at determining which shadows are likely to represent disease amenable to antimicrobial therapy

The mucosal complications of pulmonary tuberculosis which produce the distressing symptoms of tracheobronchial laryngeal oropharyngeal and intestinal tuberculosis often respond remarkably to antimicrobial therapy Such treatment is frequently justified merely to relieve symptoms even though the pulmonary disease may appear to be incurable Undoubtedly drug therapy may yield comfort and prolong the duration of life in many hopeless types of pulmonary tuberculosis

*Therapeutic Regimen* —Streptomycin (or dihydrostreptomycin) remains the most effective and most widely applicable drug for treatment of pulmonary and extrapulmonary tuberculosis but present-day practice is to recommend that it always be combined with para aminosalicylic acid (' PAS ) Several regimens are in common use the most widely accepted of which are listed below

(*1*) *Combined Intermittent Regimen* — Para aminosalicylic acid by mouth 12 0 gm or more daily (3 0 gm four times daily or 4 0 gm three times daily taken with food) and streptomycin (or dihydrostreptomycin) 1 0 gm intramuscularly every second or third day this is a regimen well tolerated by adult patients of average weight and is effective over prolonged periods

This regimen seldom yields the neurotoxic complications of streptomycin therapy The physician must recognize that though highly susceptible individuals may have some degree of loss of vestibular function after prolonged

the factor of drainage is so important that antimicrobial therapy alone should not be depended upon without bronchoscopy, postural drainage or, at times, surgical drainage Furthermore, it must be mentioned that bronchiogenic carcinoma, foreign bodies, bronchial strictures, bronchial adenomas, and rarer lesions may be the basis for any pulmonary abscess Interlobar empyema with bronchial fistula may simulate pulmonary abscess, and this was commonly seen before the day of virtually universal penicillin therapy in pneumonia

## Bronchiectasis

There is no definitive treatment for bronchiectasis except the radical surgical removal of all diseased pulmonary segments Before such operations the antimicrobial drugs are of great value in reducing the amount of purulent sputum and in improving the general condition of patients debilitated as a result of chronic pulmonary suppuration These drugs are of very great value in preventing the postoperative complications of empyema, postoperative atelectatic pneumonia, and hematogenous dissemination of the infectious process (brain abscess *etc*)

Inoperable bronchiectasis may offer insuperable obstacles which no amount or variety of drug therapy can surmount But dramatic results may be achieved by most intensive and prolonged efforts to control the mixed bacterial infection largely responsible for the distressing symptoms of the disease It is probable that the damaged bronchi never return to normal as a result of medical treatment but symptoms may be abated temporarily and when these recur as a result of reinfection subsequent treatment may yield similar results However it is rarely observed that antimicrobial therapy can accomplish its goal without the most careful coordinated program of drainage and hygienic care

Penicillin and streptomycin have retained their popularity as the most practical agents in the treatment of bronchiectasis, and frequently the sulfonamides are worthy of trial Aureomycin, chloramphenicol and terramycin may be used for brief periods if well tolerated but these are seldom useful as the primary agents over prolonged periods

Penicillin and streptomycin may be administered by the aerosol method or by intramuscular injection or both The intramuscular method of injection offers some very practical advantages, especially with penicillin, but must be used with caution with streptomycin because of the toxic potentialities of the latter drug It is suggested that a trial period of intramuscular treatment with a mixture of penicillin (600,000 units daily) and streptomycin (0 5 gm daily) be undertaken for a period of approximately two weeks If hospitalization is feasible, it is well to utilize aerosol therapy simultaneously, but, if it is necessary for the patient to remain ambulatory, aerosol treatment may be postponed until later

Aerosol therapy can never be administered satisfactorily by means of the conventional hand bulb as the source of motive power In hospitals, an oxygen tank is most convenient and is always available It is equipped with a pressure reducing valve and a flowmeter and is attached to a high capacity glass nebulizer ("Vaponephrin") with a long length of rubber tubing *It is more* economical to arrange a "Y" connector to a by pass tube which will be closed with the patient s finger when he desires the nebulizer to operate during the inspiratory phase of respiration The nebulizer is charged by adding 1 cc of distilled water to the chamber and, to this, a tablet of soluble crystalline penicillin (50 000 units) is added and permitted to dissolve Streptomycin solution (100 to 200 mg in 0 5 cc water) may be added to counteract the Gram negative bacilli especially if these bacilli have been demonstrated on sputum smears The resultant solution may be nebulized and inhaled within 15 or 20 minutes It is suggested that this performance be repeated every one or two hours while the patient is awake Such intensive therapy is much more likely to be successful than a more leisurely program

It is advisable to save all sputum and note its character each day When the purulent component has disappeared the temporary goal has been achieved Frequent Gram stained smears of sputum will give an index

# Diseases of the Kidneys

By LOUIS LEITER, M.D., Ph.D.

DISEASES of the kidney occupy a special place in medicine because of the wide variety of symptoms and signs produced in their course, the seriousness of their complications and the sequelae in other organs and systems of the body.

## RENAL FUNCTION

The major function of the kidney is the elaboration of urine. This is a *homeostatic function* set to preserve a constant internal milieu—constant as to volume of body fluid, circulating or extravascular; as to electrolyte composition individually and in toto; as to osmotic pressure; as to acid-base equilibrium; as to the waste products of protein metabolism; and as to the important nutritional elements, such as glucose, amino acids and vitamins. In addition the kidney rapidly excretes a great variety of foreign substances, including therapeutic drugs—an important factor in effective blood levels and in possible accumulation of toxic amounts during renal impairment. The kidney is believed by some investigators (Grollman *et al.*) to exert a homeostatic effect on blood pressure. The normal absence of significant proteinuria acts as a protection for plasma volume and the dynamic equilibrium of fluid exchange between intravascular and extravascular fluids. In all these functions the kidney behaves on the principle of conservation of the normal pattern of body fluids. It begins with a general ultrafiltrate of the plasma in the glomerular fluid and by selection and rejection of ions and nonionic solutes (as well as by secretion of others either from the blood or by enzymatic manufacture within the tubular epithelium—ammonia, for example) finally produces the complex mixture known as urine. Urine differs widely from the blood plasma and other body fluids, yet represents a concentrate of all that the body does not need or should not retain from the metabolism of food or tissues.

GLOMERULAR FILTRATION.—Certain aspects of renal physiology deserve special emphasis in view of their importance in clinical diseases of the kidneys. The process of glomerular filtration takes place at relatively high pressure, thanks to the arrangement of the capillary tuft between afferent and efferent arterioles, the latter being of smaller caliber and higher tone or resistance than the former. Filtration also requires a large blood flow, or inspissation would soon put a stop to it. Normally about 25 per cent of the basal cardiac output of blood per minute flows through the kidneys. The glomerular filtration squeezes out about 17 per cent of the plasma. (In infants, especially premature infants, the glomeruli are not fully developed and filtration is much lower than one would expect from the body surface area. Hence the ease with which overhydration can be produced, or nonprotein nitrogen retention.) In any clinical situation involving a decreased cardiac output, as in heart failure or shock, renal blood flow is sharply reduced and filtration suffers. However, compensatory efferent arteriolar constriction may, in time, increase the fil-

treatment this seldom occurs except in patients with defective renal function severe enough to impair ability to excrete streptomycin The resultant high level of streptomycin in the blood and tissues may produce damage to either the vestibular branch or the auditory branch of the eighth cranial nerve

The appearance of strains of tubercle bacilli resistant to either streptomycin or PAS is greatly delayed when the above regimen is employed and treatment may be continued with cumulative benefit for from four to twelve months if necessary This regimen is chosen for treatment of patients with noncritical types of tuberculosis and is used when preservation of drug sensitivity appears to be most desirable

(2) *Combined Continuous Regimen* —Para aminosalicylic acid by mouth 12 0 gm or more daily and streptomycin (or dihydrostreptomycin) 1 0 gm intramuscularly once each day this is a regimen used extensively It is preferred for more critical types of pulmonary tuberculosis or more violent complications of pulmonary tuberculosis After symptomatic or radiographic improvement it may be desirable to change to the combined intermittent regimen the latter being more likely to prevent the appearance of drug-resistant strains of tubercle bacilli

(3) *Other Schedules of Treatment* —PAS may be utilized without a streptomycin drug when preservation of streptomycin sensitivity is of paramount importance as for example when radical surgical treatment is foreseen at a remote future date after months of preparatory medical therapy

In desperate clinical circumstances the amount of streptomycin recommended in previous paragraphs may be increased to 2 0 gm daily, but usually for limited periods of time only When such doses are continued for several weeks the patient usually suffers some degree of neurotoxicity

Streptomycin drugs should always be combined with PAS whenever the latter drug is tolerated in doses larger than 6 0 to 8 0 gm daily, because of the proved ability of PAS to delay the development of bacilli resistant to streptomycin It is probable that the two drugs exert an extra therapeutic effect against tuberculosis and that the rate of improvement is accelerated as the term of effective action is prolonged

Para aminosalicylic acid frequently gives rise to uncomfortable gastrointestinal irritation which restricts the amount of drug tolerated Several preparations of PAS and sodium PAS are available Frequently it is necessary to give a patient the preparation he prefers Enteric coated preparations especially enteric-coated tablets, may not be well absorbed Granules coated with a stearate preparation and flavored to increase palatability are fully absorbed Tablets of sodium para aminosalicylate are preferred by some patients and others prefer liquid mixtures of sodium PAS which have been flavored For example

℞ PAS 100 0 gm
Sodium bicarbonate 70 0 gm
Oil of peppermint 5 – 10 drops
Water q s ad 500 cc

After effervescence has subsided each 5 cc of this mixture will contain the equivalent of 1 0 gm of PAS as the sodium salt Liquid preparations of sodium PAS are not stable at room temperature but may be kept for a few days at refrigerator temperatures

*Other Antimicrobial Agents in Tuberculosis* —The thiosemicarbazone drugs especially amithiozone (also known as Tb 1 ) have attained considerable popularity in Europe, especially in Germany Most of the observations recorded at this time were made before the observers had had the opportunity of comparing this substance with the streptomycin drugs and PAS In the United States a large majority of physicians who have studied amithiozone have concluded that it is inferior in efficacy and much more toxic than are the streptomycin PAS regimens described above However tuberculosis is a disease so variable and so prolonged in its course that physicians may need more than two or three drugs for treatment of some types of the disease Therefore it is widely believed that the thiosemicarbazone drugs may be valuable adjuncts to the more effective and less toxic preparations The circumstances requiring such treatment are not well defined but some physicians believe that tracheobronchial tuberculosis may be especially responsive to amithiozone

As to the more complex tests, the *urea-clearance determination* has maintained its popularity in recent years. It has the advantage of furnishing a blood urea estimation, a measure of glomerular filtration and, in case of average or low urine volumes, an indication of the ability of the tubules to concentrate urine. The last is given by the concentration factor or $\frac{\text{urine urea}}{\text{blood urea}}$ ratio. Though the urea clearance on the average is about 60 per cent of the inulin clearance or true glomerular filtration rate, it fluctuates considerably due to variations in back diffusion of urea at different rates of urine flow. The various formulas for urea clearance attempt to allow for this, but it is safer to ensure a good diuresis. Incomplete emptying of the bladder (with corresponding inaccurate test results) must be expected without catheterization and this is another reason for encouraging a larger urine volume during the test. Urea-clearance figures may be grossly erroneous and deceptive in the presence of bladder or ureteral obstruction, but the concentration ratio will still be helpful. The urea clearance may also be affected by prerenal influences apart from those which influence the circulation directly and glomerular filtration secondarily. Thus, a very low protein diet may reduce both the blood urea and the urea clearance to lower or subnormal level. Since in chronic diffuse renal disease there is a simultaneous impairment of both glomerular filtration and tubular reabsorption, it is not surprising that there should be a fair parallelism in general between the urea clearance and the specific gravity test. *This applies only down to the level of about* 30 per cent of normal urea clearance, at which point the maximum specific gravity has usually become fixed at 1 010-1 014, the isosthenuria level of Volhard. Further decrease in renal function—finally, to the uremic level—is still measurable by the clearance tests but no longer by specific gravity changes. It is in this range that the urea clearance is very helpful.

The battery of *specific glomerular and tubular clearances* developed by Smith, Goldring and Chasis and the investigators who followed their pioneer work with infusion techniques have made it possible to determine specific glomerular and tubular functions as well as renal blood flow and other renal hemodynamics, with an amazing degree of certainty. Unfortunately, these are essentially research tests and require unusual skill on the investigator's part and a reasonable amount of endurance on the subject's. From the practical clinical standpoint these specific clearances and their derivatives (TmPAH or the tubular excretory mass, and Tm glucose or the measure of the number of functioning whole nephrons) have served chiefly as a standard of reference, an absolute yardstick against which the cruder measures of kidney function described above have been assayed and compared with the clinical data and pathologic findings in human renal disease and in experimental renal deficiencies. The great value of the specific clearances in elucidating the role of circulatory and other prerenal factors in renal functional impairment has been beautifully demonstrated in studies on shock, congestive heart failure, diabetes insipidus, adrenal cortical insufficiency and hyperfunction and a variety of other disturbances. As a result finer changes in renal function can now be used as indicators or mirrors of metabolic disturbances in important non renal conditions such as diabetes mellitus, hyperparathyroidism, pregnancy, muscular dystrophies, hepatic disease and gout.

*In renal diseases proper certain patterns of dysfunction* emerge as dependent on the degree of involvement of different portions of the nephron. For example, in glomerulonephritis, the glomerular filtration is generally reduced disproportionately to the changes in renal blood flow or functional tubular mass, at least in the earlier stages of the disease. This pattern is what one would expect from the pathology of the glomeruli. The ratios of $\frac{\text{GFR*}}{\text{RBF*}}$ FF*, $\frac{\text{GFR}}{\text{Tm}}$ are quite low. On the other hand $\frac{\text{RBF}}{\text{Tm}}$ may be supernormal, showing relative hyperemia

*GFR stands for glomerular filtration rate, FF for filtration fraction or $\frac{\text{GFR}}{\text{RPF}}$, RPF for renal plasma flow, RBF for renal blood flow, Tm for maximal tubular function, whether for excretion or reabsorption, as a measure of tubular mass.

tration fraction to two or three times the normal thus maintaining filtration at the cost of tubular blood flow If the glomerular membrane is seriously altered by disease as in glomerulonephritis or diabetic glomerulosclerosis filtration is severely reduced even though adequate blood flow may continue through the opaque capillaries The filter pores are clogged, so to speak, and extra flow or higher pressure may do little good It is also evident that if the pre arterioles or small renal arteries are diffusely narrowed filtration cannot be satisfactory even with normal cardiac output and blood pressure The same applies to a severe constriction of the main renal artery However, if the blood pressure should rise considerably, as in the Goldblatt hypertensive animal adequate filtration pressure may be propelled into the glomeruli in spite of renal arterial resistance at the expense of increased cardiac work and its ultimate consequences

TUBULAR REABSORPTION —Tubular reabsorption is normally geared to glomerular filtration This prevents undue reabsorption of water and electrolytes by tubules attached to smaller glomeruli or excessive loss by tubules connected with larger glomeruli This balance is regulated not merely by the nephron itself but is probably subject to posterior pituitary- and adrenal cortical hormone control of renal tubular activity The process of reabsorption along with tubular excretion and tubular secretion is vastly complicated because of its specificity its sensitivity to plasma levels of the particular solute, its localization in different segments of the tubule its dependence on enzyme systems and a high oxygen supply its definite limits or maxima (*e g* for glucose reabsorption p aminohippurate or diodrast excretion, and ammonia secretion) and its relative independence of the renal blood flow or glomerular filtration rate It is not surprising, therefore that in renal disease with varying involvement of different parts of the nephron, all sorts of functional patterns may be found on appropriate testing by modern clearance techniques In isolated instances, it is possible to determine that the major dysfunction is in the distal tubule For example, in cases of nephrocalcinosis with good glomerular filtration and fair Tm for glucose, but without ability to concentrate the urine, it is possible to show that the distal tubule fails either to form ammonia in response to the stimulation of acid ingestion or to produce a strongly acid urine

MEASUREMENT OF RENAL FUNCTION —This may be very simple or quite complex The simplest over all measures of renal function are (1) the maximum concentrating ability or specific gravity of the urine under the stimulus of a low fluid intake and (2) the nonprotein nitrogen or urea and creatinine levels in the blood The former is virtually a measure of tubular function, especially of distal tubular function, the latter involves the efficiency of glomerular filtration If one adds the phenol red or phthalein test (PSP) one also obtains a crude measure of renal blood flow and tubular function (from the first 15 minute excretion of dye in addition to the total during the first hour) It is apparent that even these simple tests are subject to the influence of prerenal or extra renal factors For example, the concentration test assumes that there is no extra fluid in the body, or edema which may counteract the supposed dehydration This is often not so in renal disease with gross or latent edema or obvious or early cardiac incompetence Furthermore unless the patient has a normal protein and salts intake the urine may not even under dehydration receive enough solid wastes to produce a high specific gravity Correction of the readings for low temperature, proteinuria, and glycosuria is essential for accurate interpretation and may yield strikingly abnormal results otherwise mistaken for those of normal function In the case of nonprotein nitrogen or urea in the blood the interpretation of abnormal values must take into account the influence of variations in dietary protein fluid intake and urinary output tissue protein catabolism as altered by infection or trauma and other prerenal factors Since creatinine reflects chiefly endogenous protein metabolism, its level in the blood when carefully determined is a much more reliable index of renal function, specifically of glomerular filtration

## PATHOLOGIC PHYSIOLOGY OF RENAL DISEASES

An understanding of the normal functions of the kidney, their mechanisms of activity and regulation by intrarenal and extrarenal influences, makes the disturbed physiology and much of the symptomatology of renal diseases readily intelligible. Let us consider some of the major manifestations of clinical renal disease—proteinuria, edema, oliguria and anuria, hypertension, renal insufficiency and uremia, and the less common but important renal osteodystrophy, previously known as renal rickets or renal dwarfism when it affected children.

## PROTEINURIA

Proteinuria, one of the most important signs of renal disease, represents an increased permeability of glomerular capillaries to plasma protein. Very slight damage to the glomerular membrane results in an escape of the smallest plasma protein molecules, the albumin fraction. More severe inflammation or vascular injury would permit larger protein fractions, the globulins of various sizes and finally even fibrinogen to leak through. In fact, in the relatively mild glomerular damage associated with the uncomplicated nephrotic syndrome 90 per cent or more of the urinary protein has been found to be in the albumin fraction; in severe subacute glomerulonephritis gamma globulin and fibrinogen appear in increasing proportions and furnish a serious prognostic sign, according to Blackman *et al*. This viewpoint does not exclude the possibility, championed by Dock, Addis and Oliver and others, that even normally a small amount of plasma albumin filters out from the glomerular capillaries under the high blood pressure in them and is almost entirely reabsorbed by the proximal convoluted tubule. It has been established by repeated infusion of homologous undenatured serum albumin in man and animals that albuminuria develops and increases roughly quantitatively with the rise in serum albumin concentration even in the presence of originally normal kidneys. This also suggests normal glomerular permeability to albumin. In renal disease the tubular reabsorptive mechanism for protein may be damaged primarily or become overloaded as a result of the increased protein content of the abnormal glomerular filtrate and thus permit much protein to escape into the urine. Even if only a few milligrams of protein per 100 cc of glomerular filtrate failed of reabsorption, the total amount of protein excreted in the urine in 24 hours might easily amount to several grams in view of the normal filtration rate of about 180 liters in 24 hours. This is precisely what must happen in the nephrotic child in whom the glomeruli are scarcely altered and exhibit a normal or supernormal filtration rate but in whom every glomerulus leaks a tiny amount of protein. The highest degrees of proteinuria are found in nephrotic children. In the more severe inflammatory glomerulonephritis with obstruction to filtration and in the later stages of nephritis with marked fibrosis and disappearance of functional glomeruli the proteinuria becomes much less significant because of the great reduction in filtering surface.

The *consequences of proteinuria* are readily apparent. Within the kidney itself the precipitation of the protein (due to changes in acidity and other factors in the evolving urine) leads to the formation of casts or moulds of the tubular lumina. These casts may at times produce obstruction of individual tubules or stir up an inflammatory reaction about them to the detriment of renal integrity and function. In the circulating plasma the albumin concentration eventually falls as the drain of albuminuria continues and as the replacement by regeneration of plasma protein fails ultimately to keep pace with the loss in the urine. Once *hypoalbuminemia* has developed to the point where the protein osmotic pressure no longer can balance the hydrostatic filtration pressure in the capillaries of the body and other factors in fluid exchange no longer can compensate, *nephrotic edema* will result if salt is available. Since a dynamic balance among various factors is involved, one should not speak of a "critical edema level" of plasma albumin. However, in the absence of abnormality in venous and capillary pressure or of lymphatic drainage, it is generally true

of the tubules in striking contrast to the situation in essential hypertension or in congestive heart failure, in which the tubules are relatively ischemic In both the latter diseases, FF* remains quite high (particularly in heart failure) due to excessive efferent arteriolar constriction This constriction tends to maintain glomerular filtration in spite of severe reduction in renal blood flow Yet in hypertension the $Tm_{PAH}$ falls as the disease progresses beyond the early stage and becomes a sensitive indicator of the renal functional status, on the other hand, in severe heart failure of rheumatic origin in adults without intrinsic organic renal disease or vascular changes the $Tm_{PAH}$ and the $Tm_{GLUCOSE}$ are usually perfectly normal This contrast in maximal tubular functions may also apply to the ability to reabsorb salt and have an important bearing on the problem of edema

The various functional patterns in glomerulonephritis and other renal diseases have been carefully studied and reported by Earle *et al*, by Corcoran Taylor and Page and others The greatest usefulness of specific renal function tests is in following the course of the disease in prognosis and in gauging the effects of therapy

It is ordinarily impossible to tell from the various clearance tests whether one or two kidneys are present or there is a difference in function between the kidneys especially if such a difference is due to obstructive lesions When the question of unilateral disease or dysfunction or obstruction must be decided the most practical method is *intravenous pyelography* in which advantage is taken of renal tubular excretion and high concentration of iodinated hippuric-acid compounds or related substances Under proper conditions one kidney s function may be compared with the other s However considerable impairment in bilateral function as indicated by a low urea clearance and elevated blood urea or creatinine will affect the diodrast excretion sufficiently to render intravenous pyelography useless In many instances cystoscopy and retrograde studies are eventually necessary The use of dyes such as phenol red or indigocarmine during the latter procedure is helpful provided due allowance is made for possible differences in urine volume from the two kidneys

## Diuresis

Diuresis is not a simple process, for it may involve glomerular, proximal tubular and distal tubular functions in varying degrees The simplest type is water diuresis or very dilute urine resulting from temporary disappearance of the posterior pituitary antidiuretic hormone from the blood In this type of diuresis, only the distal tubule seems to be involved, since it can separate salt from water reabsorb the former and discard the latter anisoosmotically On the other hand when hypertonic salt or glucose solution is injected intravenously and fairly rapidly or the filterable but not reabsorbable inulin, mannitol, or sodium thiosulfate is injected in appropriate amounts marked diuresis results but it is different from water diuresis It is an osmotic diuresis due to concentration of an unreabsorbed solute in the tubular fluid with prevention of normal water reabsorption because of the energy limits of the renal tubule Sodium chloride potassium and other normal electrolytes may be washed out in the process which if severe enough may cause considerable depletion This osmotic diuresis acts all along the tubule proximal and distal The stimulating effect of intravenous injection of hypertonic solutions may also increase cardiac output renal blood flow, and glomerular filtration and so contribute another element to diuresis Finally diuresis can be produced by drugs like the mercurials by their toxic action on proximal or distal tubular function The mercurials reduce the normal reabsorbing capacity for salt and water and allow more to escape into the final urine Purine diuretics also have this effect but may also briefly increase cardiac output renal blood flow, and glomerular filtration The relative independence of water diuresis from renal blood flow and filtration in man is illustrated in the response to a high fluid (salt free) intake in patients with severe congestive heart failure

## OLIGURIA AND ANURIA

*Oliguria* exists in the adult when the daily urine volume falls to 500 cc or less. Ordinarily this is the result of inadequate intake of fluids or excessive extrarenal loss, with secondary mobilization of antidiuretic posterior pituitary hormone (which increases renal tubular reabsorption of water and produces a concentrated urine). Among the direct renal causes of oliguria are (1) decreased *glomerular filtration with more complete* tubular reabsorption of the provisional urine, whether due to glomerular inflammation, circulatory renal ischemia, intrarenal edema, or obstruction to urinary flow, and (2) toxic nephrosis with back-diffusion of filtrate through damaged or necrotic tubular epithelium. Prerenal deviation of fluid in the form of edema or ascites is an important cause of oliguria. Pain arising in the urinary tract may set up reflex oliguria by way of vasomotor changes *in renal blood flow or* release of antidiuretic hormone. Pituitary antidiuretic hormone secretion may also be increased by the action of morphine, barbiturates and other drugs. When oliguria is due to extrarenal factors and the kidneys are normal, the urinary specific gravity and color are high. The association of oliguria and a low specific gravity—less than 1.020—speaks for renal damage, whether of organic or functional origin. The occurrence of oliguria with specific gravities of from 1.010 to 1.016, approximately isotonic with glomerular filtrate, indicates severe renal functional impairment. Because of *its frequent dependence on dehydration* oliguria is commonly associated with a variety of electrolyte disturbances. Determination of the nature of electrolyte imbalance is essential for good treatment.

*Anuria* exists whenever the daily urine volume is less than 100 cc. Retention in the bladder must be excluded. Anuria is one of the most dangerous medical situations and nearly always signifies severe acute organic disease or poisoning of the kidneys, bilateral ureteral obstruction or vascular occlusion, prolonged circulatory or hemolytic shock, urinary extravasation or surgical removal of the only functioning kidney. The consequences of anuria and their treatment are described in the sections on uremia and the toxic nephroses. The vital importance of an early diagnosis of anuria and determination of its etiology is obvious.

## HYPERTENSION

Elevation of arterial blood pressure, systolic and diastolic, is a common manifestation in most of the organic renal diseases and in certain of the renal dysfunctions. The secondary effects of persistent hypertension on the cardiovascular system, including the renal arteries and arterioles, may be far more serious in time than the renal excretory insufficiency caused by *the progression of* the original disease. There is no relationship between the degree of renal excretory impairment and the level of arterial blood pressure. (*see* Chapter 24.)

## RENAL INSUFFICIENCY

*Retention of non-protein nitrogen* in the blood is a major sign of renal functional impairment and reflects reduction in glomerular *filtration*, *whether caused by organic* changes in the kidney or by altered renal hemodynamics secondary to circulatory shock or depletion of varied etiology. Of course, retention of nitrogenous metabolites may also result from obstruction anywhere in the kidney or post-renal urinary passages. The rate of accumulation of non-protein nitrogen in any case is largely determined by the numerous factors affecting protein catabolism. A high exogenous supply of protein in diet or parenteral infusion will exaggerate the degree of non-protein nitrogen retention unless the body has been severely depleted of protein and stores most of the administered nitrogen.

Similarly, high blood NPN levels will develop if trauma, surgery, infection or neoplastic disease with high fever, uncontrolled diabetes, or other reason for increased endogenous protein catabolism are superimposed on renal impairment. Yet renal function may be basically unchanged from its original level. Given a constant level of renal functional impairment, a constant rate of protein catabolism (whether of exogenous or endogenous protein), there may still be considerable fluctuations in the blood NPN concentration due to the simple and often ignored fact that the *urinary output of nitrogen wastes is partly de-*

that, in the adult, it is rare to see edema on a nephrotic base when the plasma albumin is above 2 5-3 0 grams per cent It is rare, on the other hand, not to see it when the plasma albumin is below these values if salt is given with the diet or the subject is ambulatory or is not receiving diuretic drug therapy All of this discussion of hypoalbuminemic edema assumes renal tubules capable of at least normal reabsorption of salt *If they are so damaged as to allow filtered salt to pass through them in a percentage higher than normal, the patient's problem* becomes no longer one of edema but of possible salt depletion The combination of massive proteinuria hypoproteinemia and tubular insufficiency for reabsorption of salt is virtually impossible for the first of these is rare when renal disease is so severe as to have produced the last

## EDEMA

Edema in renal disease is far more complex than the relationship between proteinuria and low plasma albumin and its osmotic pressure Within the kidney itself there is the balance between glomerular filtration and tubular reabsorption of salt a balance *entirely different from the Starling mechanism operating on a purely physical level in the general peripheral capillaries* If glomerular filtration is more impaired, absolutely or relatively in glomerulonephritis than the tubular reabsorbing function is it is easy for more complete reabsorption of salt and water to take place because of the smaller amount of filtrate Therefore the glomerulo tubular imbalance produces retention of salt and edema On the other hand when glomerular filtration is normal in young nephrotic edematous children, one must assume an actual increase in tubular reabsorption of salt beyond the normal range Here we see possible extrarenal influences on tubular reabsorption of salt, or sodium Both the antidiuretic hormone of the posterior pituitary and the adrenal cortical salt retaining steroids have been implicated There may well be other factors Certainly, the low plasma volume so constantly found with hypoalbuminemia due to proteinuria must bring into counterplay powerful compensatory mechanisms Ultimately, these must act on the nephron The kidney's excretory function is only a means to an end—conservation of body fluid and circulating volume, with proper electrolyte make up A low plasma volume however produced, should somehow act as a powerful stimulus to retention of salt and water by the kidney, even though this fluid should promptly leak out into the tissue spaces and result in edema

Apart from nephrotic edema, there are at least three other kinds of edema seen in certain renal disorders The *edema of acute nephritis* is partly due to toxic changes in *capillary permeability ascribed to the precipitating hyperergic reaction* and partly to the glomerulotubular imbalance described above In fulminating acute nephritis or *toxic nephrosis with early severe oliguria* or anuria *edema* may be a *purely mechanical* retention of excess fluids not otherwise disposable either because of virtually absent *filtration in the glomeruli or complete back* diffusion of reduced filtrate through necrotic or completely *permeable tubular walls* no longer reabsorbing or excreting selectively In both the acute and more commonly the chronic hypertensive stages of renal disease *edema* may result *from heart failure* This introduces a vicious circle since the circulatory dynamics of congestive heart failure of whatever etiology include a marked reduction in renal blood flow and glomerular filtration and corresponding defects in salt excretion and other renal functions The effects of these added handicaps on a diseased kidney are serious and difficult to counteract

One more factor of importance for both proteinuria and edema deserves mention This is *elevation of renal venous pressure* as seen ordinarily in congestive heart failure with high systemic venous pressure Proteinuria oliguria salt retention and *edema* are usually associated with severe passive congestion of the kidney *The presence of* ascites under pressure aggravates the venous disturbance in the kidney *by direct* hydrostatic effect on renal venous outflow

stages of renal diseases organic or functional *Phosphate* is also retained in severe renal insufficiency but in a much more complex manner than sulfate because of the numerous metabolic energetic processes in which phosphate is involved Furthermore the level of phosphate in the blood even with poor renal function is held in check by the precipitation of insoluble calcium phosphate which is somehow removed from the circulating blood in some colloidal form Phosphate retention also contributes to metabolic acidosis besides playing havoc with the serum calcium which is reciprocally reduced *Calcium* in addition tends to be lost in excess by poorly functioning renal tubules Hence it never accumulates in the blood in renal disease unless another factor enters—increased mobilization from bone by osteolytic disease chronic acidosis hyperparathyroidism or other hormonal disturbance vitamin D intoxication or severe immobilization of the body In these situations the flood of calcium reaching the kidneys is more than they could handle even if they were normal and precipitation of calcium phosphate within the parenchyma of the kidneys adds injury to insult creating a vicious cycle

Retention of *potassium* may occur in renal insufficiency but rarely to dangerous levels in the absence of oliguria or anuria Potassium is normally excreted by filtration and reabsorption with the difference from sodium that its excretion continues regardless of the need of the body for potassium during states of cellular depletion However should the serum level become abnormally high potassium is then actually excreted or secreted by the renal tubule as shown by the urinary potassium which exceeds the amount of potassium filtered The ability of potassium to enter cell water its participation in carbohydrate metabolism and other activities as well as its toxic effects on the heart and other muscles place it in a special category In renal insufficiency without severe oliguria low serum potassium levels may develop after prolonged vomiting diarrhea or diuresis in the presence of a low intake of potassium-containing food Since serious symptoms may arise from either high or low extracellular potassium concentration accurate measurement of serum levels is essential for proper therapy *See* Chapter 14

*Chloride* like sodium is so largely retained by the normal kidney that it would not be expected to increase in the blood in renal decompensation Furthermore loss by vomiting common in uremia is often a cause of considerable reduction in serum-chloride concentration Also the accumulation of other anions (*e g* sulfate and ketone acids) may displace not only bicarbonate but even chloride in extracellular fluids The entrance of choride into cellular water in various metabolic derangements is also believed to occur However the serum-chloride level may rise in renal insufficiency in the absence of vomiting or other extrarenal loss and produce a chloride acidosis by lowering the bicarbonate concentration even in the presence of a normal sodium value The reason for this chloride retention probably lies in the fact that the renal tubule normally has to excrete relatively more chloride than sodium for in all extracellular fluids the normal ratio of sodium to chloride in milliequivalents is roughly 150 100 or 3 2 whereas in ordinary salt as ingested the ratio is 1 1 This means that the kidney must always dispose of more chloride ion than sodium ion in order to keep the ratio in body fluids 50 per cent higher than it is in sodium chloride In certain types of tubular damage in renal diseases this selective function may be seriously impaired and chloride accumulate in the blood and all other fluids in equilibrium with it Serum chloride and sodium may both be elevated strikingly in certain diarrheas of infancy with severe dehydration and functional renal disturbance or in the rare cases of sulfathiazole or sulfadiazine nephrosis and encephalopathy in which parenterally administered saline is largely retained but water is lost from the skin as the result of high temperatures leaving hypertonic salt behind (Luetscher and Blackman)

The serum bicarbonate concentration in renal insufficiency may be normal but is generally reduced in varying degrees owing to the accumulation of other anions all of which are stronger acids than carbonic acid and therefore displace bicarbonate from its sodium partner If loss of acid gastric juice by vomiting has occurred the bicarbonate may return only to a normal level from a previously low value and still be associated with a considerable alkalosis because of the increase in ratio of bicarbonate to free carbonic acid This possibility must be borne in mind whenever the serum sodium is normal in the presence of a low chloride level obviously other retained anions inorganic or organic are preventing the expected reciprocal expansion of bicarbonate The normal close relationship and predictability of the serum sodium concentration from the sum of serum bicarbonate and chloride in milliequivalents can be severely disturbed in renal impairment just as in diabetic ketosis therefore it becomes im-

*pendent on the urine volume, hence on the fluid intake of the patient* This is true even of normal subjects because of the limit to renal tubular concentration of urea, the chief urinary nitrogenous constituent Therefore a normal individual on a high protein intake but a relatively low fluid intake and with a low urine volume will show blood urea values several times the normal in the same range as a chronic nephritic with considerable renal impairment but on a normal or subnormal protein intake The kidney is quite flexible in its functional capacity but has very definite limits in some respects The correct interpretation of the simple test—the blood NPN or blood urea concentration—requires some knowledge of the preceding factors to prevent serious errors in diagnosis and treatment

Since the non protein nitrogen of the blood consists of several known and many unknown substances of different metabolic origin and behavior in the body especially in the kidney, it is more profitable to deal with the individual constituents of this melange Urea uric acid creatinine *creatine a host of amino acids, ammonia glutathione* and other small polypeptides are involved but from the practical standpoint of renal insufficiency the first three substances are of primary interest *Urea* reflects catabolism of both exogenous and endogenous protein *uric acid* and *creatinine* especially the latter, are chiefly the end stage of endogenous or tissue protein wear and tear Hence urea excretion will be much more variable also its retention There are other significant differences All are filtered by the glomeruli but urea diffuses back in the tubules so that only from 30 to 70 per cent of the filtered amount appears in the final urine *Creatinine* once filtered does not go back into the renal blood for this reason it is an excellent measure of the glomerular filtration rate at ordinary endogenous blood levels It is, therefore not increased in the blood like urea when the patient happens to eat more protein than the average or drink less fluid On the other hand blood creatinine properly measured will accurately reflect decreases or increases in glomerular filtration regardless of the urine volume at the time Urea may be washed out of the body by forcing fluids and its formation sharply reduced by a diet high in carbohydrate but low in protein or by parenteral glucose, which produces normal blood levels even with considerable renal impairment At such times the blood creatinine will still be elevated and furnish a true index of the state of renal function Hence its great prognostic significance when a concentration of 4 or 5 times the normal value has been reached This means very severe reduction in glomerular filtration, pre uremic because presumably tubular impairment and other damage is also extensive at this stage *Uric acid* is filtered and about 90 per cent reabsorbed It accumulates readily with reduction in filtration but unfortunately its blood level is subject to many other influences such as blood cell and other cellular breakdown and hormonal changes during infection toxemia various stresses, and metabolic disturbances The simple blood uric acid level *per se* cannot therefore, be used as a reliable indicator of renal function

When the blood urea and creatinine concentrations are elevated proportionally one is primarily dealing with the effects of renal insufficiency, when the blood urea is elevated out of all proportion to the creatinine level the state of renal function is not so bad as it seems from the urea value (very likely extrarenal factors are largely responsible) when the blood creatinine is elevated relatively *higher than the blood urea* the patient is suffering not only from renal insufficiency but from the effects of protein depletion and artificial (glucose) reduction in protein catabolism (aided by diuretic washing out of urea)

*Retention of inorganic electrolytes* also occurs in renal insufficiency Here, too one must consider individual solutes because of their varying origin in the body their interrelationships in body fluids and the selective response of the renal tubules to changes in the blood levels or the amount filtered by the glomeruli As Fishberg has pointed out one would not expect increased retention during renal insufficiency of any substance which the kidney normally retains or reabsorbs almost 100 per cent from the glomerular filtrate Therefore the blood *sodium* concentration does not rise as long as the normal complement of water can be reabsorbed with it On the contrary the effects of tubular damage and acidosis are often expressed by an increased urinary loss of sodium and a diminished serum level Retention of water may dilute the sodium in the body fluids The *sulfate* ion ingested or released in the body is normally almost entirely excreted *i e* filtered and not reabsorbed just like creatinine Therefore like creatinine it will be retained and to considerable levels in the blood when glomerular filtration is impaired and the exogenous supply continues in food drugs etc The significance of this retention lies in the fact that sulfate is an acid ion displacing the weaker carbonic acid or bicarbonate ion from its sodium partner and thus contributing to renal metabolic acidosis in the late

depression of bone marrow and a somewhat increased hemolysis. This anemia does not respond to any known therapy and hence requires repeated transfusions of blood.

*Etiology.*—The early restriction of the concept of uremia to the maximal renal insufficiency of acute or chronic organic renal disease is no longer tenable. The close interdependence of renal function and circulatory dynamics, the peculiar response of renal dynamics to sudden or subacute depletion of extracellular fluids, the conversion of too prolonged functional or prerenal insufficiency into hypoxic anatomical tubular damage with clearly organic changes as the basis of the continuing uremia, and the almost entire analogy between the clinical and chemical features of so-called true uremia of organic origin and the advanced prerenal or extrarenal azotemias warrant combining the end results of all these types of renal insufficiency into the all-inclusive concept of uremia. However, the patient with functional uremia will present clinical findings of both the uremic syndrome and the precipitating underlying disease or dysfunction (*see* Page 1004). Furthermore, the treatment of uremia will naturally vary with the etiology of the renal insufficiency, but realization of the unity of renal and prerenal factors in uremia will help the physician prevent the onset of innumerable instances of prerenal azotemia and, at the same time, find the remediable prerenal factors in uremias of organic origin. For the best interests of the patients, uremia is indivisible but of multiple etiology and with multiple metabolic disturbances capable of responding to selective therapy.

*Symptoms.*—The symptoms of uremia are as varied as its origins and chemical signs and involve every system of the body. Typically, the patient with chronic renal disease at the uremic stage complains of severe anorexia and nausea and may vomit on any attempt to take food or drink. He also complains of intolerable pruritus and dryness of the skin, general restlessness, irritability, and involuntary movements of the limb muscles. Furthermore, he is subject to headache, dizziness, ringing in the ears, insomnia or unusual drowsiness, overpowering weakness and exhaustion, and heavy breathing on the slightest exertion or even at rest. He finds his mouth and throat dry. Often he has a hacking nonproductive cough, palpitation and a sense of oppression in the chest, which may change into severe precordial pain with varying radiation to shoulders and arms upon the onset of uremic pericarditis. He is conscious of vague abdominal discomfort or of actual cramps. These pains are associated with diarrhea; the stools may be streaked with blood or may be tarry. Disturbed vision, transitory or permanent; sudden temporary weakness of the limbs, difficulty in speech, and confusion as to time and place are other symptoms manifested in uremia.

The patient may first be seen in a state of semi-stupor, stupor or deep coma, the pupils contracted and the breathing deep and acidotic (Kussmaul type). Occasionally the patient may be found, his eyes rolled up, in a convulsion with opisthotonus, tonic and clonic movements and involuntary urination. Often he is found in a state of complete mental disorientation with restlessness and violent activity requiring restraint or heavy sedation.

The signs of uncomplicated uremia include brownish yellow pallor, malnutrition, wide stare, prominent eyeballs (without true exophthalmos), scratch marks and a variety of rashes (often drug induced), dehydration or edema or both (in different regions), bleeding from the nose or gums, purpuric spots (especially on the lower extremities), coarse muscular twitching or tremors along with reflex hyperirritability and muscle weakness, and occasionally tetanic spasms or positive Chvostek and Trousseau signs. There may be pulmonary rales or signs of free pleural fluid. The cardiac findings will vary with the associated condition, such as prolonged hypertension. A localized or widespread pericardial friction rub may be heard. Gallop rhythm and hemic or other murmurs are common. Kussmaul, Cheyne-Stokes or stertorous respiration may be present. Venous collapse or venous engorgement may occur depending on associated conditions and the state of hydration. The pulse rate and volume will vary with the state of the circulatory system, but relative bradycardia is not un-

perative to analyze for sodium directly if restoration of body fluid electrolytes is to be made accurately and safely

Retention of *organic acids* occurs in renal insufficiency usually as the result of starvation or complicating diabetic ketosis in which condition the ingestion or production of these acids exceeds the capacity of the body to metabolize them and the ability of the impaired kidney to excrete the excess In the absence of direct analyses for individual or total organic acids the presence of such acids in increased amount can be deduced from the discrepancy between the total base concentration of the serum or more simply the sodium figure and the sum of the determined inorganic anions or acids namely bicarbonate, chloride phosphate and sulfate and protein Ketones and lactate usually form the chief organic acids small amounts of possibly toxic aromatic acids are also retained

*Acidosis* of the metabolic type is common in severe renal insufficiency It should be added that the loss of tubular ability to secrete ammonia is an important factor in the development of renal acidosis the reduced filtration of acids by the diseased glomeruli is aggravated by the increased tubular loss of sodium and other bases through lack of ammonia production which normally tends to spare fixed base from excretion The administration of any acid-forming salts like ammonium chloride becomes a dangerous procedure under these circumstances In fact the poor response of the impaired kidney to changes in acid base balance renders the development of either metabolic acidosis or alkalosis very easy in the pre terminal and terminal stages of chronic renal disease or in the acute toxic nephroses

*Retention of water* is also possible as a result of pure renal insufficiency whether acute or chronic Although dehydration for the usual reasons is very common in renal failure retention may occur whenever the intake of fluids exceeds the outgo in the urine sweat, or gastrointestinal losses Normally however this is virtually impossible because the kidneys can excrete from 25 to 30 liters of water a day if they are forced to, as in diabetes insipidus But in severe renal disease or functional impairment the reduced glomerular filtration of water and the back-diffusion of filtered water through damaged proximal or distal tubules conspire to limit sharply the excretion of water by the kidney The daily figure may be three liters a few hundred cubic centimeters or zero (anuria) The so called polyuria of renal insufficiency is rarely more than from 10 to 15 per cent of the capacity of true polyuria by normal kidneys The retention of water on a purely renal basis is possible and edema results Its electrolyte composition may be extremely abnormal because of the loss of tubular selectivity for ions at this stage The dangers of this situation are preventable by proper management of the afflicted subject s intake of water and electrolytes This is lifesaving in acute toxic or obstructive anurias

## UREMIA

Uremia is the culmination of the metabolic disturbances resulting from complete renal decompensation whether this is a matter of days or of decades In either case the final clinical picture is the same

Essentially uremia is a clinical syndrome resulting from *severe renal insufficiency due to organic or functional causes* and embracing the whole array of fluid and electrolyte disturbances non protein nitrogen retention acidosis and other metabolic disintegration But uremia according to many competent observers is also a *toxemia* although the nature of the toxin is unknown

A number of substances from organic metabolites like guanidine derivatives to free phenols and other aromatic products of protein break down in the gastrointestinal lumen or tissue cells have been held responsible for this toxin In addition there has been a convincing array of experimental work connected with renal hypertension and its mechanisms to point toward the noxious role of renal autolytic products in the origin of vascular necrosis and other lesions in uremic animals The entire problem of the function of the kidney as a source of pressor substances on the one hand and of a normal anti pressor mechanism on the other is involved in these studies Suffice it to say that correction of the usual body fluid and electrolyte disturbances in renal insufficiency do not dispose of the under lying general metabolic derangement for which it is logical to assume that retention of some toxic substances of extrarenal (or possibly renal) origin is responsible One of the obvious major effects of the hypothetical toxemia is the *anemia of renal insufficiency* which has so far defied close analysis but is apparently compounded of

the nature of the etiological process in the kidney or elsewhere (examples are the leucine and tyrosine crystals in acute yellow atrophy of the liver and the hemoglobin derivative casts in hemolytic transfusion reactions) In chronic Bright's disease with uremia the urinary sediment may contain the very wide waxy or granular 'renal-failure' casts described by Addis as pathognomonic In the absence of a hemolytic syndrome phenolic poisoning or porphyria the urine in uremia is usually light in color for the normal urinary pigments or their precursors are seldom excreted in adequate concentration The dilute urines of uremia become more ominous when the daily volume drops to a pint or less as is often the case Casts and cells dissolve readily in these dilute hypotonic urines and this tends to make qualitative or differential diagnosis difficult Bacteriological culture may reveal infection of the urinary tract and show the kind of infection but will not alone of course point out the site of infection Chemical analysis of the 24-hour urine for sodium potassium and chloride excretion may be valuable in determining the degree of electrolyte loss and type of replacement therapy indicated Unusual urinary calcium excretion (Sulkowitch test) may point to hyperparathyroidism or vitamin D overdosage as a possible basis for uremia The finding of Bence-Jones protein in the urine of a uremic is also of considerable diagnostic value

*Treatment* —The treatment of uremia depends on the cause of the renal dysfunction Much can be done to prevent uremia especially functional uremia rapid correction of shock dehydration and electrolyte depletion usually forestalls severe renal insufficiency This requires accurate observation of the patient for signs of circulatory impairment complete measurement and recording of all urine vomitus aspirated gastrointestinal fluid and diarrheal stools with due allowance for profuse sweating and increased insensible perspiration associated with fever and dyspnea accurate tally of all fluid and electrolyte administered including blood and plasma frequent chemical analyses for serum sodium chloride bicarbonate potassium and blood NPN or urea and creatinine The proper management of diabetic ketosis or of Addison's disease in crisis requires no argument The prevention of uremia in all these conditions is largely a matter of good bookkeeping knowing accurately the intake and output of fluid and electrolytes and of maintenance of well-oxygenated circulating volume under adequate blood pressure

Prevention of uremia in severe acute glomerulonephritis and in the acute toxic nephroses including the so-called lower nephron nephrosis is essentially based on sharp restriction of dietary protein to 20 grams or less a day exclusion of salt from the diet and limitation of the potassium intake Carbohydrate and fat provide the necessary calories Up to 300 grams of glucose may be given intravenously in concentrated form if the patient is unable to retain food Treatment of actual or impending cardiac failure by the appropriate measures (except for the use of mercurials or purine diuretics) the use of BAL (dimercaptopropanol) early in mercurial nephrosis the interruption of sulfa or other drug therapy possibly responsible for the renal damage the administration of penicillin aureomycin or other antibiotics as indicated to control an underlying infection or prevent pulmonary infection in previously edematous lungs or bladder infection in catheterized patients—all these are also necessary measures for the prevention of uremia It is exceedingly important to prevent hypertensive encephalopathy or any other strain on the circulation In any case with oliguria involving the slightest doubt as to etiology the possibility of urinary-tract obstruction by calculus should be excluded by *x* ray films and if necessary by cystoscopy and retrograde urography

In older patients with congestive heart failure or hypertensive disease uremia may result from excessive sodium and chloride depletion by mercurials and rigid low sodium diets This low sodium syndrome is characterized by low serum sodium values (chloride may be normal if ammonium chloride is being given) and elevated blood-urea levels along with many of the symptoms found in early uremia Prevention of this syndrome often fatal if not recognized

usual except during acute heart failure The abdomen may be scaphoid or distended and moderately tender over the bowel The kidneys may be unpalpable or enlarged and tender Ascites may be present when there is general edema The extremities are often wasted from inactivity and weight loss and may or may not be edematous Muscle hyperesthesia is common Reflex clonus and other abnormal reflexes may be elicited Stomatitis ulcerative pharyngitis *suppurative parotitis and regional lymphadenitis* are less frequently seen in these days *of better oral hygiene*

To the above description must be added the *signs due to hypertensive vascular disease,* acute or chronic, often associated with the renal disease that results in uremia In acute glomerulonephritis or eclamptic toxemia uremia is associated with elevated systolic and diastolic blood pressure hard wiry pulse and the following eye signs narrow or irregularly constricted retinal arterioles and flame-shaped hemorrhages, cotton-wool exudates and varying degrees of papilledema or choking of the disc Other associated signs are accentuated heart tones and possibly dilatation along with the episodic findings of acute left ventricular failure or pulmonary edema or of general heart failure with venous engorgement, hepatic enlargement and tenderness In the chronic hypertensive patient evidence of cardiac hypertrophy and enlargement aortic sclerosis and dilatation retinal arteriolosclerosis and varying degrees of retinopathy and signs *of organic changes in the* central nervous system as a result of vascular *disease or accident* will be superimposed and intermingled with the syndrome of uremia to produce a complex and unhappy clinical picture

In the *functional uremias* which arise from circulatory, hemorrhagic or traumatic shock, severe infectious diseases acute dehydration from gastro intestinal obstruction aspiration by drainage tubes and a great variety of other conditions reflecting themselves in severe renal impairment the symptoms and signs of the original disease vascular accident or disturbance will be inextricably interwoven with the *symptoms* and signs of uremia *per se*

The diagnosis of uremia the *laboratory findings* must include proof of non protein nitrogen retention in the blood and evidence of impaired urinary excretion or impaired concentrating ability on the part of the kidney Some electrolyte change is almost always apparent In general uremia is usually associated with blood NPN values of 75 mg per cent or higher and with blood urea nitrogen figures of 50 mg per cent or higher The blood creatinine may be relatively less elevated or proportionately increased, depending on the cause and duration of uremia but it is never *normal as in* the azotemias unrelated to renal impairment *Until there is some specific test for a specific* uremic toxin the chemical diagnosis of *uremia* will be tricky *if taken alone The* diazo reaction for uremia and tests for indican or free *phenols are reasonably* reliable in cases of chronic uremia but are often negative in cases of acute uremia No reliance can be placed on serum-electrolyte estimations in diagnosing uremia Acidosis or alkalosis may be found, the former the more commonly However elevations of serum inorganic phosphate and sulfate when present together are a highly significant indicator of chemical uremia Electrocardiographic changes in uremia will reflect cardiac muscle hypertrophy or damage calcium or potassium disturbances pericarditis or the effects of cardiac drugs

The *urine* in uremia is characterized by relatively *fixed specific gravity* from 1 010 to 1 016 or isosthenuria due to loss of tubular concentrating *power for urea* which in spite of high blood levels may not be eliminated *at a greater rate* than that indicated by even a low daily production Urea excretion at this stage depends almost entirely on urine volume other things being equal The urine is also only weakly acid rarely less than pH 6 and contains almost no ammonia (unless there is heavy bacterial contamination of the urinary passages or the urine container) There is very little titratable acidity a reflection of *decreased* glomerular filtration of phosphates and of distal tubular *inability to convert* alkaline disodium to acid dihydrogen phosphate *There is always proteinuria* of varying degree and the urinary sediment may reflect

the nature of the etiological process in the kidney or elsewhere (examples are the leucine and tyrosine crystals in acute yellow atrophy of the liver and the hemoglobin derivative casts in hemolytic transfusion reactions) In chronic Bright's disease with uremia the urinary sediment may contain the very wide waxy or granular renal failure casts described by Addis as pathognomonic In the absence of a hemolytic syndrome phenolic poisoning or porphyria *the urine in uremia is usually light in color* for the normal urinary pigments or their precursors are seldom excreted in adequate concentration The dilute urines of uremia become more ominous when the daily volume drops to a pint or less as is often the case Casts and cells dissolve readily in these dilute hypotonic urines and this tends to make qualitative or differential diagnosis difficult Bacteriological culture may reveal infection of the urinary tract and show the kind of infection but will not alone of course point out the site of infection Chemical analysis of the 24 hour urine for sodium potassium and chloride excretion may be valuable *in determining the degree of electrolyte* loss and type of replacement therapy indicated Unusual urinary calcium excretion (Sulkowitch test) may point to hyperparathyroidism or vitamin D overdosage as a possible basis for uremia The finding of Bence-Jones protein in the urine of a uremic is also of considerable diagnostic value

*Treatment* —The treatment of uremia depends on the cause of the renal dysfunction Much can be done to prevent uremia especially functional uremia rapid correction of shock dehydration and electrolyte depletion usually forestalls severe renal in*sufficiency* *This requires accurate observation* of the patient for signs of circulatory impairment complete measurement and recording of all urine vomitus aspirated gastrointestinal fluid and diarrheal stools with due allowance for profuse sweating and increased insensible perspiration associated with fever and dyspnea accurate tally of all fluid and electrolyte administered including blood and plasma frequent chemical analyses for serum sodium chloride bicarbonate potassium and blood NPN or urea and creatinine The proper management of diabetic ketosis or of Addison's disease in crisis requires no argument The prevention of uremia in all these conditions is largely a matter of good bookkeeping knowing accurately the intake and output of fluid and electrolytes and of maintenance of well-oxygenated circulating volume under adequate blood pressure

Prevention of uremia in severe acute glomerulonephritis and in the acute toxic *nephroses including the so-called lower* nephron nephrosis is essentially based on sharp restriction of dietary protein to 20 grams or less a day exclusion of salt from the diet and limitation of the potassium intake Carbohydrate and fat provide the necessary calories Up to 300 grams of glucose may be given intravenously in concentrated form if the patient is unable to retain food Treatment of actual or impending cardiac failure by the appropriate measures (except for the use of mercurials or purine diuretics) the use of BAL (dimercaptopropanol) early in mercurial nephrosis the interruption of sulfa or other drug *therapy possibly responsible for the renal* damage the administration of penicillin aureomycin or other antibiotics as indicated to control an underlying infection or prevent pulmonary infection in previously edematous lungs or bladder infection in catheterized patients—all these are also necessary measures for the prevention of uremia It is exceedingly important to prevent hypertensive encephalopathy or any other strain on the circulation In any case with oliguria involving the slightest doubt as to etiology the possibility of urinary tract obstruction by calculus should be excluded by *x* ray films and if necessary by cystoscopy and retrograde urography

In older patients with congestive heart failure or hypertensive disease uremia may result from excessive sodium and chloride depletion by mercurials and rigid low-sodium diets This low-sodium syndrome is characterized by low serum sodium values (chloride may be normal if ammonium chloride is being given) and elevated blood-urea levels along with many of the symptoms found in early uremia Prevention of this syndrome often fatal if not recognized

early, depends on discovery of serum-electrolyte losses and replacement of these losses. Only half the necessary replacement in sodium and chloride should be administered at first and the patient's reaction, *his urine and serum-electrolyte changes* should be carefully observed. Usually, a hypertonic solution is indicated in the presence of edema to avoid overdilution of the *injected electrolyte*.

The prevention of uremia in chronic bilateral renal disease with severe functional impairment or in the pre-uremic state is based on a diet low in protein—from 30 to 50 grams of protein daily. The diet must provide enough calories to spare body protein and must provide a fluid intake of at least 3 liters a day to assure a urine volume of from 1500 to 2000 cc. and delay accumulation of non-protein nitrogen. The dietary salt intake must be restricted if edema is present. A very dilute urine like a very concentrated urine means extra work for the tubules, hence salt may be useful *when the urine is not adequately concentrated*. If the patient develops anorexia or *vomiting, parenteral fluids must be given early*. The use of acid-forming salts, alkali in large doses, mercurials or sedatives dependent on the kidneys for excretion should be avoided in the pre-uremic stage because of their harmful effects. Circulatory failure must be carefully guarded against in chronic renal disease. Acidosis must be looked for and treated with the required amounts of sodium bicarbonate or sodium citrate orally or sodium bicarbonate or sodium lactate intravenously.

The *management of uremia* is essentially *symptomatic*. *Anorexia, nausea and vomiting* usually do not yield to bland foods and small meals but often require parenteral feeding for a few days at a time to allay gastric irritability. The amount of fluid given, the type of electrolyte mixture, the use of amino acids, plasma or serum albumin, the concentration of glucose—all these will be determined by the patient's needs, the urinary output, and the serum analyses. In giving saline solutions the chloride should be diluted by the addition of sodium lactate or bicarbonate in order to maintain the 3:2 ratio of *sodium to chloride* in the normal serum. Whenever intravenous alimentation is necessary, adequate amounts of the vitamin B group and ascorbic acid should be given daily in the infusion fluid. The patient's bowel movement should be encouraged by small enemas; profuse colonic irrigations *should be avoided*. Anemia, if the hemoglobin falls below 60 or 70 per cent, may be temporarily corrected by transfusion of perfectly typed and cross-matched packed *red cells*. *No more than 250 cc. should be* given at any one time; this is easier on the patient's vascular system than 500 cc. of whole blood and furnishes the same amount of oxygen carriers.

*If the patient is oliguric and does not increase his urine volume on receiving fluids* but, instead, develops edema, there is no point to forcing more fluid into his body; only pulmonary edema, general anasarca or convulsions will result.

Adequate sedation is indicated to prevent or allay pain, nausea, respiratory difficulty, restlessness, anxiety, fear, insomnia, pruritus, twitching or convulsion. A low serum calcium is *corrected with calcium* salts given parenterally. In hypertensive *encephalopathy, careful spinal tap* and relief of pressure may be of value. Some patients soon require large and frequent doses of sedatives or hypnotics. There is no reason for withholding them if they make the patient's terminal period more tolerable. Unfortunately, many uremic individuals retain consciousness and capacity for suffering long after any prospect of even temporary remission has vanished.

The use of peritoneal or intestinal irrigation in the treatment of acute anuric uremia due to reversible renal disease has not strikingly reduced the high mortality rate. The artificial kidney or dialyzing apparatus of various types carries more promise but is still a formidable procedure because of problems of hemolysis, electrolyte and fluid balance, technical skill and other factors. However, there is reason to be optimistic about the future development of such mechanical devices.

## RENAL OSTEODYSTROPHY

This designation covers all disturbances in bone morphology resulting from osteoporosis associated with renal insufficiency. It may

be found in patients with primary renal disease (acquired or congenital organic or functional tubular) or with renal disease secondary to primary endocrine or metabolic *disturbances or to obstructive lesions in the* urinary tract. The bony changes include decalcification, loss of matrix, osteitis fibrosa and cystic changes, with pseudo fractures and deformities. Children are more strikingly affected because of the unique requirements of growing bones. The demineralization is produced in organic renal insufficiency by retention of inorganic phosphate and urinary loss of calcium in the acidosis due to impairment of renal production of ammonia. It may be aggravated by deficient dietary intake of calcium or poor absorption from the gastrointestinal tract. On the other hand, rachitic demineralization of bones may result from functional impairment of tubular reabsorption of phosphate as in the Fanconi syndrome of children or certain types of adult osteomalacia. Primary hyperparathyroidism acts early to promote renal loss of phosphate and calcium and at the same time mobilizes these substances from bone. In later stages secondary renal disease and renal insufficiency add to the pathological physiology. The degree of bone involvement in renal insufficiency is also determined by the response of the parathyroid glands to hyperphosphatemia and hypocalcemia. Over compensation may result in hypercalcemia and its consequences and in bone dystrophy of extensive degree.

*The symptoms* will depend on the duration and degree of the osteodystrophy. In children the clinical picture may be one of resistant rickets, as in the Fanconi syndrome and the group with hyperchloremic nephrocalcinosis described by Albright *et al.* The deformities of knees, ankles and wrists *originally described as due to renal rickets* and often associated with impaired growth are observed in adolescent children with advanced chronic glomerulonephritis or pyelonephritis, with polycystic kidneys or with congenital dilatation of the ureters and renal pelves and marked renal atrophy. In adults, skeletal pains or fractures may lead to *x* ray examination of the bones and disclosure of the osteoporosis and other changes even before renal insufficiency is suspected. In many uremic individuals the osteoclastic involvement of bone is revealed only at autopsy when systematic *examination is stimulated by the finding of* hyperplastic or adenomatous parathyroid glands.

*Treatment* of renal osteodystrophy will vary with the underlying disease. The treatment can be *preventive* to the extent that renal insufficiency and acidosis can be counteracted. When ammonia formation is inadequate, sodium citrate or bicarbonate is given daily in amounts sufficient to correct hyperchloremic acidosis and maintain normal serum sodium levels. Hypophosphatemia in the Fanconi syndrome is treated with dietary supplements of phosphate and extra vitamin D. Hyperphosphatemia in renal insufficiency may be reduced by diet high in calcium, low in phosphate and by *administration of large doses of aluminum* hydroxide gel to prevent absorption of phosphate. In children vitamin D in doses up to 5000 or 10 000 units daily may help to elevate the serum calcium to normal levels. Dihydrotachysterol (AT-10) may be more effective in some cases. Hyperparathyroidism, if primary, is dealt with surgically; secondary hyperparathyroidism can be treated only by management of renal insufficiency and phosphate retention.

## PATHOLOGY OF RENAL DISEASES

The pathology of diseases of the kidneys is a large subject in itself and will be discussed only insofar as it throws light on the classification and pathological physiology of renal diseases. Certain conditions, such as embolic infarction of the kidney, neoplasms and cystic transformation, hemorrhages in the parenchyma in scurvy, hemophilia or various purpuras and lymphomas, hydronephrosis or pyonephrosis due to obstruction of pelvis or ureter, focal scarring due to old inflammatory or vascular atrophy of tissue and replacement fibrosis, toxic necrosis, nephrolithiasis of various types, caseating tuberculosis or pyogenic suppuration—these and other gross conditions can be readily diagnosed on inspection after a little experience and correlated with the clinical data on

the patient However, recognition of certain forms or stages of chronic glomerulonephritis, amyloidosis, diabetic glomerulosclerosis even chronic pyelonephritis and hypertensive nephrosclerosis may be difficult from the gross description alone of the enlarged or reduced kidneys, the nature of the cortical markings the apparent amount of fat or other infiltrate, the smoothness or granularity of the surface and the coloration Histologic sections must be depended upon for differential diagnosis especially in the older age groups in which vascular disease may be superimposed on the basic renal pathology Even after studying the microscopic slides an estimate as to renal function during life may be highly hazardous in view of the role of hemodynamic factors not

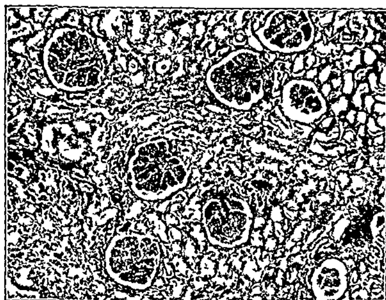

FIG 160 —Acute proliferative glomerulonephritis Note large cellular glomeruli and normal tubules Photomicrograph low magnification (Bell s Renal Diseases )

FIG 161 —Severe acute hemorrhagic glomerulonephritis from a case of bacteremia* The capsular spaces and tubules are filled with erythrocytes Photomicrograph (Bell s Renal Diseases )

registered in the kidney sections. The relative degrees of glomerular and tubular damage are even more difficult to assess anatomically unless one studies numerous nephrons teased out in their entirety by the ingenious technique of Oliver. In view of these difficulties it becomes unreasonable for either the clinician or the pathologist to expect a close correlation between functional and anatomical changes. However it is not at all unwarranted for both to expect that a fairly accurate diagnosis should be possible from an adequate clinical history, physical and laboratory findings, and an opportunity to observe carefully at least a part of the course of the disease. The reason for this is that the various diffuse diseases of the kidneys do have an individual life

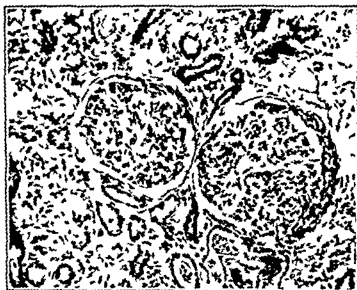

Fig. 162.—Subacute glomerulonephritis. Nearly all the glomerular capillaries are completely closed and there is severe diffuse tubular atrophy. Photomicrograph. (Bell's Renal Diseases.)

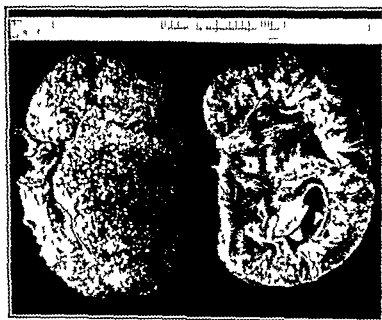

Fig. 163.—Chronic azotemic glomerulonephritis. Contracted kidney. (Bell's Renal Diseases.)

history or biologic course, even though there may be considerable overlapping in symptoms signs and pathological findings The overlapping is often due to hypertension which may initiate a whole evolution of functional and organic cardiovascular abnormalities

One serious defect of pathological material obtained from cases of chronic renal diseases is that it usually represents the last stages of the disease (uremia)

On the other hand accidental disclosure after death from some other cause, of early renal lesions in individuals not suspected of having kidney disease is of relatively little value in correlation studies The actual histology of mild acute glomerulonephritis that ends in recovery, of moderate nephritis that lasts for decades of recurrent acute pyelonephritis in its earlier attacks or the beginnings of glomerulosclerosis—these and other pathological renal phenomena are still much of a mystery to the pathologist because the material is unavailable for study, except by means of biopsies difficult to obtain This is a field worth developing like hepatic biopsies in recent years

## CLASSIFICATION OF RENAL DISEASES

The following classification of renal diseases is modified from the classical contributions of Bright Gull and Sutton Volhard and Fahr, Addis and Oliver Bell, Fishberg, and many others It differs from the earlier groupings however in including the functional renal diseases in addition to the organic types

### Classification

A Organic Renal Diseases

1 Glomerulonephritis, diffuse—acute chronic
2 Glomerulitis focal—toxic embolic thrombotic allergic
3 Glomerulosclerosis—arteriolar (hypertensive) diabetic
4 Glomerulonephrosis—amyloid lipoid pregnancy
5 Pyelonephritis—acute chronic
6 Vascular—arterio arteriolosclerotic (hypertensive) occlusive allergic toxic
7 Tubular nephroses (necrotizing)—toxic, hemodynamic, endocrine or metabolic, hemolytic obstructive
8 Congenital malformations—polycystic kidneys
9 Nephrolithiasis
10 Neoplasms—benign malignant

B Functional Renal Diseases

1 Glomerular arteriolar constriction—proteinuria hypertension cardiac failure constrictive pericarditis toxemia of pregnancy early shock
2 Tubulovascular syndrome—severe shock acute tubular hypoxia of other origin
3 Tubular hormonal—diabetes insipidus adrenal cortical disease or dysfunction, hypertension(?), adaptation to stress parathyroid disease pregnancy
4 Tubular, enzymatic—renal diabetes Fanconi syndrome dietary effects hypertension(?) drug effects
5 Venous congestion—postural proteinuria, cardiac failure

## DIAGNOSIS IN RENAL DISEASES

Diagnosis in renal diseases is based on a knowledge of the natural history of each disease, of the pathological process in the kidneys of the pathological physiology and the resulting symptoms and signs and the urinary changes characteristic of some renal diseases

*The Urine* —The urine reflects the pathological renal process provided the products of renal inflammation or degeneration have access to the urine Completely scarred glomeruli and obliterated tubules cannot affect the urine nor can interstitial inflammation if tubular walls have not been broken through by the cellular infiltrates or bacteria On the other hand since the urine has to pass through the postrenal urinary tract before it reaches the centrifuge tube and the microscope, it may pick up evidence of disease or irritation anywhere along the way including material from the prostate, epididymis seminal vesicle uterus and vagina In many cases the history will disclose symptoms clearly referable to the lower urinary tract and aid the examiner in interpretation of the urine or in the decision to obtain specimens by catheterization of the bladder particularly in the female Other important aids include the technique of collecting urine in 2 or 3 containers during a single voiding, to determine the urethral or bladder origin of pus shreds or gross blood voiding of urine before and after prostatic or seminal vesicular massage and cystoscopic examination ureteral catheterization and x ray contrast studies

The *gross appearance* of the urine may be diagnostic for example of hematuria hemoglobin

uria (or methemoglobinuria) porphyrinuria melanuria alkaptonuria bilirubinuria certain drugs and dyes in the urine uric acid and urates pyuria and other abnormalities In other instances careful chemical tests may be necessary

For *microscopic study* the freshly voided urine is the best specimen to examine unless it is dilute or alkaline Formed elements rapidly dissolve in such urine and even proteinuria may fail of detection unless very careful acidification is carried out Ideally the best urine to examine is that obtained under conditions of dehydration as in the Addis concentration test This means having the patient eat the normal solid articles of diet—meat potatoes bread butter cream eggs cheese cereals desserts sugar salt etc—but avoid all liquids 5 or 10 per cent carbohydrate vegetables and juicy fruits for 18 hours If an Addis count is to be made on the urinary sediment the 12 hour urine (from 9 P M to 9 A M ) is collected in one container However if the patient voids before retiring and saves the urine passed on arising in the morning it will be satisfactory for qualitative examination This urine should have a maximum specific gravity be strongly acid and contain formed elements in a good state of preservation Centrifugation at a low or moderate speed for a few minutes will produce a good sediment sufficient for diagnostic purposes without the need for an accurate Addis count which requires a fair amount of technical experience The important thing is that the physician obtain a urine as though for an Addis count and then examine the sediment himself He will be rewarded by a wealth of findings in urines from patients with renal disease Absence of red cells leukocytes and casts in a highly concentrated (above 1 026) acid urine, properly centrifuged and prepared for microscopic study is strong evidence against active renal disease Satisfaction with negative reports on urines of variable reaction and of specific gravities ranging from 1 010 to 1 018 or so is risky especially in the presence of proteinuria or of a recent history of abnormal urines

*Proteinuria* by the usual clinical tests may be present in traces in normal urines containing secretions from the accessory sex glands in the male or female The amount of protein in urine is helpful in differentiating renal disease from disease of the lower urinary tract In the former much more protein is found relative to the number of leukocytes or red blood cells in the sediment This is understandable in view of the larger amount of protein that may leak out through the millions of damaged glomeruli in diffuse renal disease In inflammations of the lower urinary tract the proteinuria is derived from a relatively small amount of exudate diluted by the entire urine volume However this is only a relative distinction and does not help much in diagnosing diffuse diseases of the kidney in stages with little proteinuria for one reason or another In judging the quantitative significance of proteinuria the concentration of the particular urine specimen must be taken into account This is often neglected in conclusions from changes in the number of plusses or grades of proteinuria on different occasions Quantitative analysis for protein in a 12 hour or 24 hour urine collection is essential in all patients with considerable proteinuria or lowered serum protein values in order to determine the need for extra protein in the diet However a marked proteinuria may diminish sharply in patients on a low protein intake

It may be useful in certain cases to test the urine specifically for *serum globulins* as an index of the severity of the renal pathology especially in glomerulonephritis and amyloidosis Ordinarily the urinary protein consists of about 90 per cent serum albumin and only small amounts of the globulin fractions The percentage of globulin has been reported to be much higher in the more severe types of glomerulonephritis as confirmed by autopsy observations The specific *Bence-Jones proteins* in the urine of patients with multiple myeloma and other diffuse bone diseases are readily detected by their peculiar heat solubility It is good routine in any laboratory equipped with a 56 60 water bath to place in this bath all urines that show even slight clouding well before the boiling point as the heat and acetic acid test is carried out When the sulfosalicylic acid reagent is used in the cold specimen there is all the more reason for warming up the precipitated urine to 60 in order to detect Bence Jones proteins They are not infrequently associated with ordinary serum proteins in the urines of older patients with multiple myeloma

Proteinuria is only an indicator of renal dysfunction altered glomerular permeability or diminished tubular reabsorption of filtered protein It is therefore not limited to organic renal diseases but is in fact a frequent accompaniment of numerous infectious diseases toxemias circulatory failure allergic reactions and other disturbances affecting the general body economy Postural proteinuria is very common in children

*Hematuria* is perhaps the most important single urinary abnormality because it may be grossly visible to the layman and therefore immediately calls attention to the existence of urinary tract disease But it is also nonspecific to a large extent because any inflammation trauma congestion neoplasm ulceration calculus or gravel—from the kidney on down to the urinary meatus—may give rise to gross or microscopic hematuria To list the possible causes of hematuria is merely to list every disease of the urinary tract plus every systemic cause of hematuria such as all hematological disorders with disturbances in coagulation or capillary fragility vitamin C deficiency allergic reactions of bac

terial or drug origin and various types of toxemia and septicemia. However in chronic glomerulonephritis and renal vascular disease, hematuria is of great significance as a measure of the activity of the inflammatory process in the glomeruli or of acute vascular obliteration or allergic process.

*Hematuria*, almost always microscopic, is the chief criterion of the numerous varieties of glomerulitis and may lead to the first suspicion of the underlying general disease or toxemia. The characteristic of *glomerular hematuria* is that some of the red cells or their *breakdown pigments may be trapped in* casts as they pass down the renal tubules. This obviously cannot occur in the case of bleeding distal to the nephron and is therefore *of high diagnostic value in localizing the* source of the bleeding. *Red blood cell casts* often contain only the ghosts of erythrocytes. Erythrocytic ghosts are also found free in the urine and *in fresh concentrated acid* specimens suggest renal parenchymal origin, whereas normal looking hemoglobin filled red blood cells are more likely to derive from the lower urinary tract. The use of a catheter to obtain the specimen from the bladder, and especially the ureter, may give rise to slight traumatic microscopic hematuria. *The finding of a single authentic* red cell cast is of significance. In all cases, however, the urinary sediment if not grossly bloody should be tested for blood with the *guaiac or the benzidine reagent*.

*Cylindruria* or casts in the urine may be a valuable diagnostic and prognostic index. Casts are formed by precipitation of filtered *plasma protein in the distal and collecting* tubular lumen, aided by the pH, the chemical action of chondroitin sulfuric acid, the salting-out effect and other factors (Oliver). *In these hyaline or waxy casts, granules of* cytoplasmic protein extruded from degenerating tubular epithelium or granular conversion of desquamated renal cells become imbedded to form granular casts. Similarly epithelial casts arise from desquamated but still recognizable tubular epithelium. Erythrocytic casts have already been mentioned. *Leukocytic* or pus casts develop in pyelonephritis and at times in severe acute glomerulonephritis. Finally there are the refractile fatty casts containing renal epithelial cells *or granules with both neutral* isotropic fat and the *doubly refractile, or anisotropic, lipoids*. These last are of great diagnostic importance in differentiating chronic glomerulonephritis, amyloidosis and diabetic glomerulosclerosis, on the one hand, from the large group of cases of pyelonephritis and hypertensive or arteriosclerotic renal vascular disease on the other. This simple but valuable aid to diagnosis has not been sufficiently utilized in spite of many years of acquaintance with it, by experts in the field of renal diseases. Similar value attaches to the finding of free floating fatty cells in the urinary sediment. The presence of brownish red granular *pigment casts* should arouse the suspicion of glomerular bleeding or of the products of intravascular hemolysis and hemoglobinuria. Special stains for iron (Prussian blue reaction) may reveal hemosiderin in casts or epithelial cells in the sediment and aid in the diagnosis of pernicious anemia, hemochromatosis or hemosiderosis of various origin. In the absence of severe dehydration and sluggish urine flow due to acute febrile or metabolic diseases, wide casts of any variety usually spell uremia because they are found in cases of extensive parenchymal destruction. They form in the great ducts of Bellini at the very end of the collecting system (Oliver).

*Pyuria* is next to proteinuria the most common urinary abnormality. It usually indicates an active infection or *inflammation* in the urinary tract. It may occur as many individual leukocytes or leukocytes in clumps, masses or shreds of entangling mucus. *Pus casts are also seen when the* cells enter the urinary stream in the tubular lumen directly from interstitial infiltrates or from the glomeruli.

The less the proteinuria associated with pyuria, the more likely the lower urinary tract is the source of the leukocytes. Of course contamination with vaginal contents and prostatic or seminal vesicular secretion must be guarded against. When the urine is grossly cloudy and full of shreds, examination of the uncentrifuged sample is better as a measure of the amount of leukocytic component. The cells are in various stages of preservation and may be polymorphonuclear or mononuclear. They may show highly motile granules when specially stained (Sternheimer). The simultaneous presence of bacteria, bacillary or coccal, in the freshly voided specimen is strong evidence of infection as the basis of the pyuria.

The reaction of the urine and the ammonia content determined by urea-splitting organisms furnishes a clue to the type of bacteria involved. *Cultures* must be made to determine the nature of the microörganisms and to serve as a necessary guide for antibiotic therapy. The tubercle bacillus should always be remembered. The presence of pus in the urine requires the simple 2 or 3 glass test to determine the possible source in the anterior or posterior urethra. When this structure is excluded (and the glands draining into it) the problem is shifted to the bladder, ureters and renal pelves. The possibility of an obstructive lesion as the basis of secondary infection in the urinary tract is the first thought that should enter a physician's mind when he discovers pyuria in a patient with or without other symptoms. Much harm has been done by neglect of this simple fact.

*Crystalluria* may or may not be important. The sediment of many normal urines may contain crystals depending on the concentration, reaction, temperature and many other factors in the particular specimen. Thus a highly acid concentrated urine of a patient with fever and some dehydration may deposit a heavy mass of brick red urate crystals as it cools. Gentle warming may redissolve them. The alkaline urine of a nervous patient shortly after a meal may yield much triple phosphate material on centrifuging. Alkaline carbonates which effervesce on acidification and heating of the urine, oxalates that come down in nearly neutral urines, are common normally.

Whether a given sediment or repeated samples from the same patient contain an excess of uric acid, calcium-oxalate or calcium phosphate crystals, possibly related to the problem of urinary lithiasis or gravel, is usually very difficult to determine without other diagnostic information. On the other hand, various *sulfa* crystals in fresh urines, especially when associated with erythrocytes or their ghosts, may be of vital significance in assessing the danger of precipitation of these drugs in the urinary tract. Similarly, *cystine* crystals point to cystinosis and possible cystine lithiasis. The rare leucine and tyrosine crystals indicate severe hepatic damage. Bence-Jones protein and other interesting compounds may crystallize in the standing urine.

*Hemoglobinuria.*—Hemoglobin is found in the urine either as the result of secondary hemolysis after hematuria or as the direct effect of intravascular hemolysis and glomerular filtration of the free hemoglobin or other blood pigment derivatives.

While hemoglobin is reabsorbed by the normal renal tubule, the capacity is limited and the excess hemoglobin escapes into the urine, where it can be identified by the gross coloration and spectroscopic examination. Often pigment casts are present in the urinary sediment. The absence of hematuria is characteristic in true hemoglobinurias. Whenever hemoglobinuria is detected a sample of the patient's blood should be drawn under proper precautions for the determination of the presence of free hemoglobin in the serum. If the patient's hemoglobinuria is related to exposure to cold, prolonged exercise (march hemoglobinuria), nocturnal occurrence or allergy to fava beans (favism), specific induction of hemolysis may be the only way of proving the diagnosis.

Apart from its chemical and cellular content, the urine may furnish information by way of volume, diurnal distribution, frequency of expulsion and pain associated with the act. *Oliguria* and *anuria* have already been discussed (page 993).

*Dysuria.*—Dysuria or painful urination is often associated with frequent or urgent passage of urine. It may indicate inflammation, ulceration or congestion anywhere from the kidney to the external meatus. If occurring only at the beginning and end of urination, the seat of trouble is likely to be in the neck of the bladder. Continuous pain throughout urination speaks for urethral disease. Dysuria may be associated with renal or ureteral colic in urinary lithiasis or passage of blood clots. Prostatic hypertrophy in the male is a common cause of dysuria and frequency of urination. Cystitis and prolapse of the uterus in the female are very common. Dysuria brought on by bowel movement suggests prostatitis or seminal vesiculitis.

*Nocturia.*—Nocturia, apart from excessive intake of fluids during the evening or just before retiring, is an index of delayed renal excretion of water ingested or injected. This is most commonly the result of gross or occult cardiac failure, with latent edema developing during the hours of activity in the upright posture. With recumbency, excess fluid in the interstitial spaces re-enters the circulation and is made available to the kidneys. Furthermore, renal blood flow is increased during the recumbency and rest of the night hours, favoring increased urine formation. Nocturia may also be due to pri

mary renal impairment, usually advanced, with inability of remaining tubules to respond rapidly to diurnal changes in water content of the blood. Finally, nocturia may be post renal and associated with hydronephrosis or irritation of the bladder by infection, prostatic hypertrophy, diverticula, nervous system lesions or pressure by abdominal masses. In young children nocturia is likely to become enuresis. Though this is an expression of nervous tension and emotional conflicts, it also accompanies a variety of congenital anomalies and secondary inflammation or obstruction of the urinary tract.

Difficulty in starting the act of urination, incontinence of various degrees, changes in the caliber of the stream during its flow, intermittent stoppage with or without distress, retention for varying periods, splitting of the stream—all these are usually indicative of obstructive lesions in the bladder or urethra or of neurogenic disturbance in the motor function of the bladder and its sphincters. They require careful investigation of both the lower urinary tract and the patient as a whole.

## PROGNOSIS IN RENAL DISEASES

About 90 per cent of the children with acute glomerulonephritis completely recover but only 50 per cent of the adults with the disease recover. The severe hypertensive disease associated with unilateral atrophic pyelonephritis in the first 2 or 3 decades of life may be completely cured by nephrectomy, whereas in later years the same treatment usually fails. Early recognition of urinary tract obstruction and its surgical relief may put an end to recurrent attacks of pyelonephritis and progressive destruction of renal tissue. Antibiotics can have no more than a temporary effect on urinary tract infection in the presence of persistent obstruction.

The prognosis of uremia due to acute toxic or circulatory nephrosis is much better with proper management of the patient's water, electrolyte and nutritional requirements than is the prognosis of uremia due to severe acute glomerulonephritis. In the former case, circulation can still be reestablished in the glomeruli within two weeks or less; much tubular regeneration may occur. Very little can be done about polycystic kidneys directly, but fortunately in many cases, the destruction of renal tissue is slow enough to be compensated by hypertrophy of less involved nephrons. In practically all of the functional diseases of the kidney, appropriate therapy is of considerable value, provided the associated or underlying general disease or trauma does not in itself dominate the prognosis unfavorably. The prognosis of renal neoplasms and of various serious pyogenic infections of the kidney is almost entirely a function of early recognition.

## ACUTE DIFFUSE GLOMERULONEPHRITIS

In its acute form, acute diffuse glomerulonephritis is acute Bright's disease or acute hemorrhagic nephritis, characterized by the post infectious onset of gross hematuria, facial and other edema, hypertension, cerebral manifestations and changes in the blood and urine. The chronic form is simply a continuation of an unhealed, often unrecognized acute nephritis or its subsequent exacerbations.

*Etiology and Pathogenesis.*—The beta hemolytic Group A streptococcal infections account for at least three fourths of the cases of acute diffuse glomerulonephritis and by the same token for most cases of the residual chronic types of the disease. Usually the upper respiratory tract, including the accessory sinuses, is the focus of infection, but the focus of infection may be in the lungs, the seat of secondarily infected tuberculous cavities, bronchiectasis, suppurative pneumonia or lung abscess. It may also originate in pyogenic (streptococcal) infections of the skin such as impetigo, erysipelas, wound infections, ulceration of various types, and infected burns. The focus of streptococcal infection may in rare instances be in osteomyelitic bones, in infected lymph nodes in various parts of the body, or in the gastrointestinal or the genital tract. Other pyogenic organisms such as the pneumococcus, the streptococcus viridans and the non hemolytic streptococci

found on infected heart valves and in the blood stream in subacute bacterial endocarditis (and very rarely the gram negative pathogenic cocci) may be responsible for glomerulonephritis in a few cases The occurrence of true glomerulonephritis in bacillary infections or spirochetal septicemias has not been clearly established except for syphilis nor is there any evidence as yet of a possible viral origin of glomerulonephritis Acute glomerulonephritis as a result of oak sensitization has recently been discussed as a possibility by Rytand

The historical role of the chilling of the body in the etiology of acute glomerulonephritis is well established but must be reinterpreted as a predisposing factor to hemolytic streptococcal respiratory infections It is difficult however on this basis to explain cases in which hematuria and edema develop within a day or two of exposure to chilling or immersion Lacking accurate clinical data on the important matter of preceding respiratory infection the burden of proof lies with those who accept the coincidence at face value

Because of the prevalence of hemolytic streptococcal infections in children acute glomerulonephritis has its maximum incidence in the first two decades It may occur however at any age

The *pathogenesis* of glomerulonephritis is bound up in an immunologic reaction between a streptococcal kidney protein antigen of some sort and the corresponding autoantibody The combination of the antigen and its antibody in the glomerular endothelium presumably sets off the inflammatory reaction This theory is based largely on the Masugi experimental nephrotoxic nephritis and on *in vitro* demonstration by the Cavelti of autoantibodies to streptococcal kidney antigen There are serious objections however to applying the animal data to the human disease The immunologic theory is highly satisfying but still not conclusively proved The delay of at least a week or two between the acute streptococcal infection and the earliest clinical signs of nephritis so clearly documented in the older observations on scarlet fever nephritis is best explained by the time required to build up sufficient antibody for the allergic reaction in the kidney The parallelism to acute rheumatic fever is striking Yet though the same bacterial agent is involved and the antistreptococcal immunologic response is similar in the two diseases acute *glomerulonephritis is only infrequently associated* with acute rheumatic fever In the solution of this puzzle may lie the solution of the basic problem of selective localization of allergic responses to infection

*Symptoms and Course*—Acute diffuse glomerulonephritis may begin in the postinfectious period of a hemolytic streptococcal disease in a variety of ways There is the onset with vague lassitude headache a little nausea or anorexia perhaps some lumbar muscle pain and low fever (often attributed to the preceding infection) The erythrocyte sedimentation rate is elevated and there is often a polymorphonuclear leukocytosis of moderate degree If at this point the urine is examined carefully proteinuria and significant microscopic hematuria and cylindruria including some erythrocytic casts will be found These urinary changes also undoubtedly occur without any obvious symptoms and can be detected only by routine analysis the second week after an infection It is from this large group of nonspecific symptomatic or asymptomatic cases of acute glomerulonephritis that a great many cases of chronic nephritis of various types arise masquerading as idiopathic insidious or nonspecific chronic glomerulonephritis For every clear cut typical clinical case of acute glomerulonephritis there are probably at least ten subclinical cases most of them milder than the average full blown case

In the obvious case the disease may begin with gross hematuria or brown red smokiness of the urine puffiness of the face swelling of the feet and ankles or general increase in weight a noticeable reduction in urine volume at times a sensation of burning on urination headache (especially on awakening) nausea or vomiting general abdominal discomfort and distention dull aching or more severe pain over the lumbar regions In children projectile vomiting or generalized epileptiform convulsions may characterize the onset Cough difficulty in breathing palpitation oppression in the

chest or an acute attack of "asthma" together with great anxiety and profuse expectoration of pinkish frothy mucoid sputum, may develop early. Blurring of the vision, bleeding from the nose, or purpura of the skin may occur.

*Physical examination* will reveal a variable amount of waxy pallor, moon face with *swollen, translucent eyelids, both upper and lower and often, some edema of the scleral conjunctiva.* The tongue is usually coated and the breath may be foul or ammoniacal. The throat and tonsils may show evidence of recent inflammation and the *cervical lymph* nodes draining this region may be enlarged, tender or even fluctuant with pus (though this is extremely unlikely in these days of antibiotics). If the patient has had scarlet fever, erysipelas, impetigo, scabies or surgical wound infection, the appropriate skin lesions will be evident. The blood pressure may be normal or moderately or markedly elevated; the diastolic level may be disproportionately increased. The pulse may be hard and wiry, the heart rate either relatively slow with an elevated blood pressure *or more ominous increased.* The size of the heart is usually normal but in cases with signs of acute congestive failure, general enlargement may be found. The same is true of cases with pericardial effusion. The neck veins may be engorged and the antecubital venous pressure elevated. Orthopnea is common in both these situations. Deep breathing may be associated with acidosis but usually this does not occur during the first week. The heart tones may be normal, accentuated or distant depending on the associated conditions. Gallop rhythm of either type *is common in cases* with severe hypertension or signs of left ventricular failure. Other arrhythmias are unusual. The lungs are usually clear but *may show* residual bronchitic signs. Basal rales or generalized moisture is part of acute left-ventricular failure. The abdomen may be non contributory but on occasion is distended and tympanitic and may be tender in the epigastrium. In severe instances bowel sounds may be absent as the result of reflex or paralytic ileus. There may be moderate costovertebral tenderness and the kidneys may be palpable and sensitive. The liver is enlarged and tender in cases with congestive failure. The extremities may show a rather solid, tender edema, this edema may even involve the forearms and the hands. Reflexes are often hyperactive in the patients with hypertensive cerebral symptoms, and after convulsions, abnormal responses are obtained. Muscular hyperesthesia may be elicited in cases with profuse vomiting and dehydration. The ocular fundi are normal in the average case, but in patients with severe or sudden rises in blood pressure blurring or choking of the discs may develop *rapidly along with marked general narrowing* and localized transitory spasms of the retinal arterioles, venous engorgement, retinal edema, and striate hemorrhages. Subretinal detachment may occur after numerous convulsions.

The *urine* is usually grossly bloody or smoky or shows a frankly bloody sediment on standing or centrifugation. The volume is ordinarily reduced to 500 cc. or less for 24 hours but may still reflect the intake in mild or moderate cases. In severe inflammation of the glomeruli oliguria or anuria may set in within a few days. *Proteinuria* is usually marked but there are rare cases in which the proteinuria is only slight and sometimes even absent. The low salt content of the urine may interfere with the detection of traces of protein, hence a few drops of a saturated salt solution should be added to the urine before it is heated or the protein chemically precipitated. In addition to numerous erythrocytes and casts of all varieties, except for the doubly refractile lipoid type (never seen in the first few weeks of an initial attack of nephritis), there may be many *leukocytes, even in cast form.* The urine is usually strongly acid early and may show a high specific gravity in the first few days. Later even with oliguria the specific gravity falls, depending on the degree of renal tubular impairment. The persistence of a high specific gravity during oliguria in acute nephritis strongly suggests extrarenal dehydration, especially in the absence of edema.

*Kidney function* as measured by retention *in the blood of non protein nitrogen* and its individual fractions will usually show some *degree of impairment.* Glomerular filtration

is disproportionately reduced in relation to renal blood flow In severe oliguria uremic levels heightened by extrarenal factors may develop within a few days If the urine is bloody the PSP test is impractical otherwise it is a fairly sensitive measure both of the early impairment and of the early recovery stages The maximum urinary specific gravity or renal concentrating ability is quickly reduced in acute nephritis and is the last function to return to normal during recovery it lags weeks or months behind the PSP or urea-clearance test even when the patient is on a nearly normal diet as to protein and salt The renal excretion of water is usually not seriously impaired except in cases with severe oliguria although the response to a dilution test may be markedly delayed The excretion of salt is of course reduced whenever edema develops such reduction indeed is often the immediate cause of the edema In severe oliguria or anuria administered salt is completely retained and rapidly leads to increase in body fluids and circulatory embarrassment unless disposed of by abnormal extrarenal losses

During the course of acute glomerulonephritis three *complications* of major significance may arise hypertensive encephalopathy cardiac failure and uremia The first of these does not necessarily carry a serious prognosis the second does the last uremia is likely to be fatal

In *hypertensive encephalopathy* severe headache often general or occipital and associated with vomiting usually precedes the convulsive seizure In children the convulsion may apparently come out of a clear sky and be the first indication of glomerulonephritis after a streptococcal infection Visual disturbances blurring or scotomata or the seeing of flashes of light may precede or follow the seizure and may persist if hypertensive retinal edema develops The blood pressure is usually high or increases before the convulsion Convulsions may be repeated until serious or fatal circulatory or respiratory depression occurs Between seizures the patient may be comatose or semistuporous or restless and agitated and subject to mental aberration The temperature may rise considerably if the convulsions occur in short order Ordinarily however, the encephalopathic syndrome can be controlled by appropriate sedation

*Cardiac failure* in acute nephritis is most likely to occur in patients with mounting blood pressures or with sudden sharp hypertension and patients who continue to eat salted foods Left ventricular failure may occur suddenly as acute pulmonary edema with impending asphyxia The patient may turn ashen or livid with shock and die unless quickly treated for acute heart failure Acute hydropericardium or pericardial effusion along with hydrothorax may produce considerable dyspnea and venous congestion in acute nephritis This is usually of more gradual onset than acute left ventricular failure The picture of complete congestive heart failure with swollen tender liver engorged neck veins cyanosis and dilated heart with poor tones or gallop rhythm is found in patients with massive edema whose treatment has been neglected and in patients with acute myocarditis

*Uremia* in acute glomerulonephritis usually occurs after a few weeks of oliguria or several days of anuria Extrarenal components due to vomiting and diarrhea may be prominent and hypertensive encephalopathy or cardiac failure may be superimposed to produce a complicated situation In this type of uremia in contrast to that of chronic renal disease the patient s sensorium is usually not clear and the entire picture is more suggestive of a general toxemia Hemorrhagic phenomena are likely to develop in the skin the nasal and gastrointestinal mucous membranes the retina and the central nervous system A rapid anemia is common Acidotic breathing and coma compete with muscular twitchings and convulsions for the finale Once uremia has followed anuria in acute glomerulonephritis death almost always results

*Prognosis* —The prognosis in acute diffuse glomerulonephritis depends on the patient s age the severity of the pathological process and functional impairment the heart s response to the strain of both the disease and its treatment and the time of recognition of the disease

chest or an acute attack of "asthma" together with great anxiety and profuse expectoration of pinkish frothy mucoid sputum, may develop early. Blurring of the vision, bleeding from the nose, or purpura of the skin may occur.

*Prognosis* —The prognosis in acute diffuse glomerulonephritis depends on the patient s age the severity of the pathological process and functional impairment the heart s response to the strain of both the disease and its treatment and the time of recognition of the disease

Complete recovery from an initial attack of nephritis in childhood occurs in 90 per cent of the cases. The remaining 10 per cent include the acute cases of the disease and cases of uncured, hence eventually chronic, nephritis. When acute glomerulonephritis *first develops in adult life, the outlook for* complete recovery is on the average not better than 50 or 60 per cent and the incidence of unhealed chronic active nephritis approximates 30 or 40 per cent. The prognosis is much poorer in the rarer cases of initial acute nephritis in those past 50. Complete recovery probably never occurs *if the disease attacks kidneys already the seat of hypertensive or arteriosclerotic vascular* disease or senile atrophy.

When acute glomerulonephritis is so severe at the onset as to produce anuria apart from extrarenal factors or heavy globulinuria the pathology usually includes extensive obliteration of the glomerular capillaries by both endothelial proliferation and massive exudation and hemorrhage into *Bowman's capsule followed by extracapillary* epithelial and fibroblastic crescent formation. The prognosis is always grave in these cases because of the irreversibility of the process and the immediate depression of renal function.

*Cardiac failure*, whether left ventricular or general, is very serious in cases of acute nephritis and is responsible for about 25 *per cent of the deaths. It is dangerous not* only in itself but also through its hemodynamic effects on the renal dysfunction already present.

*Early recognition* of the disease through urinalyses after acute streptococcal infection leads to the institution of proper treatment, especially of bed rest. This may well prevent acute cardiac failure and other complications. *Whether early bed rest really has* much to do with complete recovery from early nephritis has recently been questioned by Rudebeck on a statistical basis. Most *observers agree* with Volhard, however, that chronic nephritis rarely develops in a patient put under medical care early during his initial attack of nephritis. Bed rest seems to be the chief reason for this, since various kinds of diet therapy have been used in conjunction with it and yet led to the desired result.

*Treatment.*—Bed rest and keeping the body warm are imperative until the major clinical signs and symptoms have disappeared. This usually takes several weeks *or months. The prevention of acute glomer*ulonephritis is based on the control of hemolytic streptococcal diseases, especially during mass exposure of susceptible children and young adults. Once a streptococcal sore throat is suspected, penicillin should be given immediately (300 000 units intramuscularly) and the dose repeated at intervals *of from 6 to 12 hours to suppress the antigen and the subsequent antibody* response. Repeated dosage of penicillin during the first few days of the infection is more important than the individual dose. The penicillin treatment of scarlet fever is based on a similar principle. When the antibiotic is given several times a day, antistreptolysin production can be completely suppressed and complications prevented.

*The prevention of some of the major* manifestations of acute nephritis—the vascular crises, heart failure, edema and nonprotein nitrogen retention—is a major concern. The common measure for the first three is the rigid dietary restriction of salt or sodium in any form. At the same time the fluid intake is limited to the volume of urinary output plus an allowance of from *500 to 1000 cc for normal extrarenal loss of* fluid. Sodium restriction prevents edema, delays cardiac failure and has an antihypertensive effect. Sedation with barbiturates, preferably those independent of renal excretion, or with 25 or 50 per cent *magnesium* sulfate given intramuscularly in repeated doses (controlled by frequent checks of the blood pressure, reflexes and respiratory rate) is valuable in preventing hypertensive seizures and reducing headache. Patients not subject to nausea may be given magnesium sulfate in doses of from 4 to 30 cc at the necessary intervals. Vasodilators of the *veratrum viride group* or papaverine given parenterally have also been successfully employed, the former may give rise to unpleasant gastrointestinal or circulatory reactions. Warm baths or diaphoretic procedures with proper replacement of

fluids lost by sweating have been relatively little used recently but can be fairly effective as a sedative and vasodilator procedure for patients with hypertensive symptoms Exposure to chilling and circulatory stress must be carefully avoided if hydrotherapy is employed

Prevention of non protein nitrogen retention becomes important in direct ratio to the severity of the acute nephritis and the degree of oliguria The goal is to reduce both protein intake and endogenous protein catabolism to a minimum This can be done by limiting the diet to carbohydrates and fats yet furnishing enough calories to prevent breakdown of body glycogen and protein or taking advantage of the protein sparing action of glucose In case of anorexia vomiting or inability to swallow because of stupor or coma intravenous glucose in 15 to 25 per cent solution is indicated Adequate vitamin B complex and vitamin C must always be administered with diets high in glucose The non protein nitrogen in the blood will still rise if there is severe oliguria but at a much slower rate Furthermore the acidosis caused by phosphates and sulfates associated with protein catabolism will be materially inhibited In the presence of anuria all electrolytes must be carefully excluded from the diet to prevent serious disturbances in body fluid volume or composition Specific electrolytes are given only to replace losses as indicated by chemical analysis of the serum

*Symptomatic treatment* in acute nephritis is a matter of relieving pain headache nausea vomiting insomnia and other minor symptoms by the usual simple measures In mild uncomplicated cases with good renal function only moderate restriction of dietary protein is indicated In the absence of hypertension or more than slight proteinuria rigid salt restriction is not necessary In severe cases one must consider the treatment of acute heart failure of generalized edema of respiratory distress or obstruction of oliguria and anuria of convulsions of acidosis and other electrolyte disturbances In addition to rigid or complete sodium restriction and sharp reduction of fluid intake the treatment for *acute cardiac failure* includes absolute bed rest in the semi upright posture for respiratory comfort the administration of oxygen by nasopharyngeal catheter or by mask or tent the administration of morphine or other hypnotic in adequate dosage venesection if the veins are acutely engorged the application of tourniquets to the limbs if anemia contraindicates blood removal the intravenous administration of digitalis glycosides or strophanthin preparations for rapid action on the myocardium This emergency cardiac treatment should not include aminophyllin or mercurial diuretic drugs These two potent agents are contraindicated in acute nephritis because the kidneys cannot respond to them and may be irritated or severely damaged by the drugs

The *edema* of acute glomerulonephritis may require treatment if extensive enough or in certain locations Obviously, restriction of sodium and fluid will limit the development of edema and will easily control it under average conditions Pleural fluid sufficient to embarrass respiration is rare but requires aspiration The same applies to the occasional ascites under tension Hydropericardium may be very difficult to distinguish from acute cardiac dilatation but when recognized may require tapping Edema of the glottis may require intubation or tracheotomy as an emergency Edema of the brain associated with hypertensive encephalopathy and increased intracranial pressure may necessitate cautious removal of spinal fluid (if this is done the danger of herniation into the foramen magnum must be borne in mind)

The treatment of *anuria* consists in attempting to restore urine formation while reducing the effects of urinary suppression on the metabolic processes Since prerenal or extrarenal dehydration or electrolyte depletion as the result of vomiting diarrhea or prolonged anorexia may at times be responsible for anuria in acute nephritis a careful history and appropriate serum chemical analyses are indicated This is particularly important in the absence of edema or pulmonary rales or the presence of slight edema and signs of dehydration In case of doubt it is permissible to administer up to 3 liters of fluid including one liter of physiological saline or saline plus lactate in

a ratio of 3 to 1, during the first twenty-four hours The response of the urinary output to this amount of fluid may reflect the presence of dehydration If there is no increase in urine volume no serious harm will have been done by the excess of fluid on one day If anuria persists for more than a few days the use of an "artificial kidney or dialyzing apparatus is definitely indicated, especially for hyperpotassemia provided an experienced group of physicians and the necessary facilities are available Otherwise it is essential to maintain the patient on carbohydrate and fat, without protein, without electrolytes of any sort unless symptomatic acidosis requires specific treatment, and on the minimal amount of water necessary to cover extrarenal losses

## CHRONIC DIFFUSE GLOMERULONEPHRITIS

When acute glomerulonephritis fails to clear up within a few weeks or months the possibility of chronic nephritis looms up to alter the prognosis Actually it is difficult to determine when the nephritis becomes chronic Residual microscopic hematuria and proteinuria may outlast other signs and symptoms of acute nephritis by months or even a year or two Until they disappear or are otherwise explained one cannot safely assume that the patient has recovered Once such recovery has occurred however permanent immunity is virtually assured for there are no authenticated cases of a second attack of glomerulonephritis It is therefore impossible to diagnose chronic glomerulonephritis within less than a year after the onset of the initial acute attack, unless gross symptoms and signs of active renal disease continue in addition to the urinary changes

Chronic glomerulonephritis is always an active process in the sense that it proceeds relentlessly, although at extremely variable rates While the term *latent* is often used loosely to designate a grossly asymptomatic chronic nephritis or, in the more exact sense a stage during which renal function blood pressure and urinary signs remain stationary or constant at any given level for some months or years, one should not be deceived by its apparently harmless connotation A latent chronic nephritis, properly defined does not proceed to healing, it simply moves more slowly than the more active types toward the inevitable stage of advanced renal insufficiency To avoid confusion and disappointment it is, perhaps, best not to think in terms of latent nephritis at all

*Etiology and Pathogenesis*.—Chronic glomerulonephritis is always the result of an unhealed episode of acute glomerulonephritis and therefore has the same etiology as the latter The inflammatory destruction of glomeruli, the atrophy of tubules and the secondary renal vascular changes combine to produce the various clinical forms

*Symptoms and Course*.—The patient with heavy proteinuria and reduced serum protein level will develop an edematous or *nephrotic* course and the associated nutritional and biochemical disturbances This will never be a pure lipoid nephrosis for there will always be evidence of glomerular inflammation in the urine even though the blood pressure and renal function as ordinarily determined may be normal In a few years the nephrotic type will develop into *mixed* chronic nephritis Ultimately the nephrotic edema and hypoalbuminemia may recede as renal insufficiency progresses and the patient enters the pre-uremic stage with moderately elevated or severely hypertensive levels of blood pressure The *hypertensive* non-edematous form of nephritis may be associated with relatively slow deterioration in renal function but is characterized eventually by the cardiac cerebral and retinal complications of hypertensive disease These may in turn accelerate the renal-disease process and final uremia In some patients the entire course of chronic glomerulonephritis is run with little edema or hypertension and with urinary findings of a minimal degree Nevertheless, after some decades severe renal impairment results These patients may not seek medical care or receive an accurate diagnosis for years because of the paucity of gross findings Nutrition may remain good because of lack of dietary restriction Yet anemia supervenes whenever renal failure has reached a sufficient degree of severity Growth and development in children may proceed normally in the pre-uremic stage

Otherwise some form of renal rickets or dwarfism may arise In the *course* of chronic glomerulonephritis *exacerbations* often occur which may be attributed to intercurrent infections usually hemolytic streptococcal or less clearly to renal hemodynamic disturbances secondary to minor or major surgery pregnancy trauma exposure or subjection to renal irritants Usually such an exacerbation is heralded by an increase in proteinuria and hematuria, gross or microscopic within a day or two of the precipitating factor A more gradual decrease in renal function may occur over a period of weeks a slow but often incomplete return toward the control level follows Edema rise in blood pressure headache malaise anorexia vague abdominal pain and some frequency of or irritation upon urination may or may not appear Only careful urine-sediment and renal function studies under controlled dietary conditions will reveal the true course of the disease

The course of chronic nephritis to uremia or other termination may be fairly rapid a matter of a few years or take from 2 to 4 decades especially if the onset occurs in childhood Since acute nephritis is essentially a disease of children and young adults it is unusual to encounter chronic glomerulonephritis even at autopsy past the age of 50

*Differential Diagnosis* —Chronic glomerulonephritis is to be distinguished from proteinuria and hematuria of non nephritic origin and from other forms of bilateral renal disease Only amyloid glomerulonephrosis and diabetic glomerulosclerosis can imitate the nephrotic type of nephritis in the adult Other characteristic findings in the first two diseases will serve to differentiate them from this nephrotic type In children the distinction between nephrotic nephritis and genuine nephrosis is not merely academic the latter carries a better prognosis than the former In genuine nephrosis there is complete absence of signs of glomerular inflammation and renal impairment over a fairly long period The differential diagnosis between chronic hypertensive nephritis and chronic pyelonephritis in later stages may be difficult in the absence of typical histories or abnormal pyelographic findings Yet the presence of doubly refractile lipoid cells and various types of casts in the urine will establish the diagnosis of chronic nephritis even when there is a confusing and superimposed infection of the lower urinary tract Similarly, anisotropic fatty cells and casts are not found in the urinary sediment of patients with essential hypertension or arteriolar nephrosclerosis In addition the combination of chronic hypertension and a normal urea clearance or other measure of glomerular filtration regardless of proteinuria is common in the earlier years or decades of essential hypertension and virtually unknown in chronic glomerulonephritis Polycystic kidneys are usually recognized on palpation or *x* ray The various types of chronic glomerulitis associated with general vascular diseases and chronic granulomatous infections should be differentiated from chronic glomerulonephritis as should the hypertensive renal toxemia of the last trimester of pregnancy Chronic congestive heart failure with severe passive congestion of the kidneys may imitate or obscure a more or less burned out' chronic glomerulonephritis Multiple myeloma occasionally enters the differential diagnosis of chronic glomerulonephritis because it may give rise to microscopic hematuria Tests for Bence-Jones protein in the urine *x* ray studies of the bones and aspiration of the bone marrow for myeloma cells will ordinarily settle the diagnosis Hyperparathyroidism rarely produces chronic renal insufficiency without nephrolithiasis or nephrocalcinosis but secondary hyperparathyroidism in chronic nephritis may produce a syndrome confusing even to the experts Finally bilateral renal vein thrombosis (a rare condition) may mimic the nephrotic syndrome or hypertensive nephritis with uremia

*Prognosis* —Recovery from chronic glomerulonephritis is always out of the question except in the few cases of the nephrotic type in children or young adults in whom no hypertension nor renal impairment is ever manifested Most chronic nephritics die of uremia About a third of the patients however die of cardiac failure or cerebral vascular accident before uremia sets in The prognosis of chronic glomerulonephritis is determined chiefly by the level of renal

function at the time of diagnosis and by the rate at which the disease progresses during the first few years

*Treatment* — Chronic glomerulonephritis should be prevented during acute nephritis Ideally, this should include some means of sharply reducing the amount of streptococcal antigen believed to initiate the immunologic chain in acute glomerulonephritis All patients with acute nephritis should be treated with penicillin or aureomycin until hemolytic streptococci are completely eradicated from the nose and throat or cutaneous foci Nitrogen mustard has been used experimentally to suppress the production of antibodies but its clinical effectiveness is still undecided although remissions of clinical activity of early chronic nephritis have been reported in a carefully studied but small series of cases (Chasis *et al*) Antihistaminic agents are of no value here nor has cortisone been demonstrated to be of value The importance of prolonged bed rest has been stressed

*Symptomatic* treatment of chronic nephritis is concerned with the maintenance of adequate nutrition within the limits of the renal functional capacity, and the management of edema or hypertension Apart from acute exacerbations the patient may be allowed ordinary reasonable physical activity without undue exposure to chilling He may engage in occupations not involving strenuous exertion or exposure to cold In the case of a woman pregnancy should be discouraged but may be permitted to continue if already under way provided renal function is only slightly reduced and the blood pressure only moderately elevated Any aggravation of symptoms should be an indication for interruption of pregnancy

The diet in chronic nephritis varies with the point of view of the physician For those who believe that *protein* is damaging to the kidney, a low protein diet (0 5 gm per kilo of body weight) with addition of extra protein for urinary loss or growth will be the regimen of choice even when renal function is still quite good However the administration of a more liberal diet containing from 0 7 to 1 gram of protein per kilo of body weight daily for the adult (and proportionately more for the nephritic child) is more practical and has not been shown to damage the kidneys There is higher proteinuria on diets high in protein than on diets low in protein but the difference is unimportant within the range of from 0 5 to 1 gm of protein per kilo of body weight a day and is far outweighed by the patient s improved nutritional status on the better diets When renal function falls to the preuremic level reduction of protein intake to the lower level (0 5 gm per kilo of body weight a day) is indicated

Apart from protein the diet in chronic nephritis should be normal unless the patient is edematous in which case the salt intake must be restricted Terminal uremic edema presents a very difficult problem for even water excretion is severely impaired at this point In dealing with low salt diets in *chronic nephritis, the problem of loss of* appetite and nutrition must always be weighed carefully against the possible benefits of the regimen The indiscriminate restriction of salt indicates a lack of understanding of how the kidney works It is *more important to maintain the patient s* tissues and strength than to follow traditional routine

Stubborn *nephrotic edema* necessitates a more liberal protein intake up to 1 5 grams per kilo of body weight a day for the adult *for restoration of the depleted body protein* It is however almost impossible to increase the serum albumin by increased protein in the diet as long as heavy proteinuria continues from damaged glomeruli A diet high in protein (more than 100 grams or so a day) *is useless here* It should be remembered that approximately 30 grams of tissue protein must be formed before 1 gram of serum protein is added It takes months on a good diet to bring about a significant rise in the serum protein concentration The *food protein should have* a high percentage of animal protein Adequate calories promote weight and prevent waste of protein energy must be furnished by carbohydrate and fat Since the lipemia and the hypercholesterolemia of the nephrotic syndrome are neither clearly related to nor influenced by the fat content of the diet there is no reason for restriction of lipids

The electrolyte disturbances in nephrotic edema associated with malnutrition may

involve low serum sodium increased serum chloride normal or low serum bicarbonate and variable serum potassium Tissue potassium depletion may exist and there is some reason to believe that sodium and chloride may be abnormally distributed in intracellular fluids All these changes justify the carefully controlled use of *mixtures of sodium and potassium* bicarbonate citrate acetate or lactate in amounts calculated to restore the normal electrolyte composition of the body fluids No hard and fast rules can be laid down for the exact amounts to be given since they depend on the biochemical findings before treatment and on the response to the administration of salt mixtures However renal insufficiency of significant degree excludes this type of treatment In successful instances diuresis and removal of edema may result in others alkalosis or hyperpotassemia may occur or temporary increase in edema This kind of treatment is not yet feasible for the general practitioner requires frequent serum and urine analyses Potassium salts should not be given if renal function is considerably impaired or oliguria is present and fails to respond to increased fluid intake

The use of *diuretic drugs* in nephrotic edema is not very successful but is indicated after empiric trial Purine drugs are of little value and soon cause gastrointestinal trouble and anorexia Potassium nitrate from 10 to 15 gram dosage daily may increase diuresis on a low fluid low salt intake and keep mild or moderate edema under control The organic mercurial diuretics with or without the synergistic effect of ammonium chloride or nitrate are not nearly so effective in nephrotic edema as in cardiac edema but should be tried unless there is considerable hematuria or other sign of fairly active or recent renal inflammation Renal function should not be less than 30 or 35 per cent of normal by the urea-clearance test and the maximal specific gravity corrected for proteinuria not less than 1 018 or 1 020 A good diuretic response is the best index of safety in the use of mercury in chronic nephritis

Attempts to elevate a very low serum albumin by means of concentrated plasma are impractical in adults because of the large amount required and the salt content In young children, however such attempts have sometimes succeeded The use of *salt poor human serum albumin* for this purpose is wasteful and expensive for most of the protein runs out into the urine Nevertheless it is indicated in very edematous anorexic and malnourished children to tide them over a bad period even if only temporary diuresis is obtained The harmlessness of repeated serum albumin injection is not entirely established

The use of *gum acacia* gelatin or other macromolecular solution for osmotic effects and diuresis in nephrotic edema has its advocates and opponents The occasional or intermittent infusion of these compounds is not dangerous and may be quite effective temporarily but the possibility of hepatic infiltration—with acacia for example if used repeatedly in quantity— must be borne in mind particularly in the case of children

In children there are two important complications of the nephrotic syndrome One is the *peritonitis* often pneumococcal complicating ascites and now readily controlled by *penicillin* The symptoms may not be dramatic therefore smears and cultures of peritoneal fluid should be made whenever the child has abdominal pain tenderness variable distention low fever or unusual anorexia or bowel disturbance The other complication is the metabolic state with signs of peritoneal irritation associated with a sharp fall in the amino-acid level of blood or plasma This *nephrotic crisis* ' is part of a severe nutritional change and can be alleviated promptly by the intravenous administration of amino acid mixtures or protein hydrolysates The possibility of potassium depletion in nephrotic children with persistent diarrhea must be remembered

*Hormone treatment* of nephrotic edema whether for diuretic or general effects has never measured up to the enthusiastic claims made for thyroid parathyroid testosterone and other products In the case of thyroid extract the large doses necessary for significant diuresis may give rise to diarrhea or have toxic effects Parathyroid hormone is not indicated for the reduced serum calcium attributable to low serum

function at the time of diagnosis and by the rate at which the disease progresses during the first few years

*Treatment* — Chronic glomerulonephritis should be prevented during acute nephritis Ideally, this should include some means of sharply reducing the amount of streptococcal antigen believed to initiate the immunologic *chain in acute glomerulonephritis* All patients with acute nephritis should be treated with penicillin or aureomycin until hemolytic streptococci are completely eradicated from the nose and throat or cutaneous foci Nitrogen mustard has been used experimentally to suppress the production of antibodies but its clinical effectiveness is still undecided although remissions of clinical activity of early chronic nephritis have been reported in a carefully studied but small series of cases (Chasis *et al*) Antihistaminic agents are of no value here nor has cortisone been demonstrated to be of value The importance of prolonged bed rest has been stressed

*Symptomatic* treatment of chronic nephritis is concerned with the maintenance of adequate nutrition within the limits of the renal functional capacity, and the management *of edema or hypertension* Apart from acute exacerbations the patient may be allowed ordinary reasonable physical activity without undue exposure to chilling He may engage in occupations not involving strenuous exertion or exposure to cold In the case of a woman pregnancy should be discouraged but may be permitted to continue if already under way provided renal function is only slightly reduced and the blood pressure only moderately elevated Any aggravation of symptoms should be an indication for interruption of pregnancy

The diet in chronic nephritis varies with the point of view of the physician For those who believe that *protein* is damaging to the kidney a low protein diet (0 5 gm per kilo of body weight) with addition of extra protein for urinary loss or growth will be the regimen of choice even when renal function is still quite good However the administration of a more liberal diet containing from 0 7 to 1 gram of protein per kilo of body weight daily for the adult (and proportionately more for the nephritic child) is more practical and has not been shown to damage the kidneys There is higher proteinuria on diets high in protein than on diets low in protein but the difference is unimportant within the range of from 0 5 to 1 gm of protein per kilo of body weight a day and is far outweighed by the patient s improved nutritional status on the better diets When renal function falls to the pre uremic level, reduction of protein intake to the lower level (0 5 gm per kilo of body weight a day) is indicated

Apart from protein the diet in chronic nephritis should be normal unless the patient is edematous, in which case the salt intake must be restricted Terminal uremic edema presents a very difficult problem for even water excretion is severely impaired at this point In dealing with low-salt diets in chronic nephritis the problem of loss of appetite and nutrition must always be weighed carefully against the possible benefits of the regimen The indiscriminate restriction of salt indicates a lack of understanding of how the kidney works It is more important to maintain the patient s tissues and strength than to follow traditional routine

Stubborn *nephrotic edema* necessitates a more liberal protein intake, up to 1 5 grams per kilo of body weight a day for the adult for restoration of the depleted body protein It is however almost impossible to increase the serum albumin by increased protein in the diet as long as heavy proteinuria continues from damaged glomeruli A diet high in protein (more than 100 grams or so a day) is useless here It should be remembered that approximately 30 grams of tissue protein must be formed before 1 gram of serum protein is added It takes months on a good diet to bring about a significant rise in the serum protein concentration The food protein should have a high percentage of animal protein Adequate calories promote weight and prevent waste of protein energy must be furnished by carbohydrate and fat Since the lipemia and the hypercholesterolemia of the nephrotic *syndrome* are neither clearly related to nor influenced by the fat content of the diet there is no reason for restriction of lipids

The electrolyte disturbances in nephrotic edema associated with malnutrition may

eventually lead to varying usually moderate, renal functional impairment and some degree of hypertension In the periarteritis nodosa or polyarteritis group the combination of glomerular inflammation and renal arteriolar or arterial disease may produce all the signs and symptoms of severe diffuse renal disease At times this renal involvement may furnish the first clue to the nature of a puzzling disease characterized by fever, wasting enlargement of the liver spleen and lymph nodes and negative results in tests for bacterial infection or lack of response to antibiotics In the chronic forms of focal glomerulitis careful and repeated search of the urine sediment for doubly refractile lipoid cells and casts will be rewarding and diagnostic

*Etiology and Pathogenesis* —The etiology and pathogenesis of focal glomerulitis vary with the responsible disease In the bacteriemias and septicemias, there may be bacterial or fibrin emboli focal capillary thrombotic lesions focal necrosis and reactive inflammation In the hyperergic vascular diseases the glomerulitis is presumably a local expression of a general vascular allergic inflammation comparable to foreign protein sensitization The fundamental nature of this reaction is still shrouded in mystery The net result however is glomerular capillary damage leading to hematuria and followed by healing or focal glomerular fibrosis If the glomerulus and its arterioles are sufficiently compromised the corresponding tubule will be rendered ischemic and undergo various types of degeneration and atrophy The effect on renal function will depend on the number of focal injuries to nephrons and the degree of final scarring

*Diagnosis* —The diagnosis is based on the association of some general infection or allergic disease with the typical urinary changes The chief problems in differential diagnosis are presented by acute or chronic diffuse glomerulonephritis and urinary tract bleeding due to blood dyscrasias urolithiasis tumors or other lesions from the renal pelves on down In general it is safest to consider diffuse glomerulonephritis as the basis for proteinuria hematuria and cylindruria until it can be reasonably excluded Many patients with ' focal nephritis have wound up with uremia some years later because they really had ordinary diffuse glomerulonephritis without early hypertension edema, or renal impairment Even subacute bacterial endocarditis classically responsible for focal embolic or thrombotic glomerulitis was associated in the pre-penicillin period with diffuse glomerulonephritis in about 10 per cent of the more prolonged cases

*Prognosis* —The prognosis in focal glomerulitis is determined by the underlying disease In acute bacteriemias complete cure is possible A few focally scarred glomeruli do no harm In subacute bacterial endocarditis serious renal damage may occur if the diagnosis is delayed After antibiotic therapy the patient may succumb to renal insufficiency from a combination of gross infarcts and glomerulitis of extensive nature In the allergic vascular diseases and visceral lupus erythematosus the glomerulitis and associated arteriolitis and arteritis may lead to uremia

*Treatment* —Treatment is not directed specifically at the glomerulitis but at the responsible disease or toxemia Antibiotics blood transfusions and hormones (*e g* ACTH or cortisone in visceral lupus) are used as indicated for the specific situation

## GLOMERULOSCLEROSIS—ARTERIOLAR (HYPERTENSIVE) AND DIABETIC

Glomerulosclerosis may be part of arteriolar nephrosclerosis secondary to essential hypertension or hypertensive renal vascular disease or may be the renal sequel of diabetes mellitus A combination of the two forms clinically and pathologically is common in the older age groups

## ARTERIOLAR GLOMERULOSCLEROSIS

Arteriolar glomerulosclerosis or nephrosclerosis usually has a background of essential hypertension It is therefore the most prevalent renal disease among older people

*Etiology and Pathogenesis* —The etiology varies with the theory of the physician as to

proteins, since the ionized calcium is usually adequate Testosterone may be beneficial in favoring nitrogen retention and formation of tissue protein, but its salt retaining action is a serious drawback unless the diet is very low in salt Reports of favorable results from cortisone are still too meager to warrant general use of this hormone in nephrotic nephritis If there is anything hormonal that the nephrotic patient needs it is either adrenocortical insufficiency with regard to salt and water-retaining hormones or increased adrenal production of a diuretic steroid

The treatment of the *hypertensive syndrome* in chronic glomerulonephritis is based, to a considerable extent on the same principles that underlie the management of essential hypertension even though the mechanism involved is probably different The removal of nervous and emotional stimuli to the vasomotor system is helpful in any type of hypertension so is the control of physical activity, obesity and other such factors However, since chronic nephritic or renal hypertension is supposedly humoral in origin sympathectomy is practically never indicated nor is it demonstrably effective in this condition As to the Kempner rice diet or other regimen very low in sodium it may have its value for hypertensive nephritic patients with edema and nitrogenous waste retention or in episodes of hypertensive encephalopathy and retinopathy but it is dangerous to employ for patients with a salt losing tendency That these diets have any beneficial effect on renal function *per se* remains to be established Vasodilator drugs apart from the relief of anginal pain or acute hypertensive headaches, are relatively unimportant in hypertensive nephritis It is essential however to follow the cardiac status closely and to deal as early as possible with impending left ventricular failure by employing digitalization, rest salt poor regimen, and other standard measures

*Anemia* is a frequent accompaniment of chronic nephritis If nutritional in origin it may be overcome with iron or protein supplements But if it results from severe protein depletion of the nephrotic stage the quickest and most effective way to combat it is by means of whole blood transfusions In the later stage of severe renal impairment anemia is partly due to the toxic depression of hemopoiesis Blood transfusions, repeated as necessary, offer the only way to make up this deficit The blood is best given in the form of packed red corpuscles to avoid overloading the circulation It is sufficient to maintain the hemoglobin at 70 or 80 per cent of normal to alleviate symptoms of anemia and of overwork on the part of the heart Meticulous typing and cross-matching are necessary for even a slight hemolytic reaction may prove very dangerous to a patient with renal function already at a low level In the hypertensive type of chronic nephritis, severe epistaxis or gastrointestinal bleeding may result The blood loss may require prompt replacement in the usual manner Very rarely prothrombin deficiency is a factor in the tendency to ecchymoses in the skin or mucous membranes in advanced renal insufficiency This is treated with vitamin K given parenterally or with fresh whole blood transfusions

## FOCAL GLOMERULITIS

Focal glomerulitis (focal glomerulonephritis) is really a pathological diagnosis and rather risky to make clinically if it is implied that it represents a rather harmless form of glomerular disease productive only of hematuria gross or microscopic without hypertension, edema or renal functional impairment In this chapter the term is used to include the glomerular lesions occurring in association with acute or chronic bacteremias allergic or hyperergic vascular diseases and the so called collagen diseases like visceral or disseminated lupus erythematosus The clinical expression of focal glomerulitis is hematuria with variable proteinuria and cylindruria Erythrocyte or blood pigment casts indicate the glomerular origin of the bleeding In the acute types the underlying disease usually a severe *acute infection or septicemia* is the dominant feature the renal involvement is detectable only by urinary study In the more chronic type—for example in subacute bacterial endocarditis and in visceral lupus—the progressive glomerular damage may

and Wilson is the specific renal disease of diabetics young and old. It is a major cause of death among diabetics. It causes death by way of uremia.

*Etiology and Pathogenesis*.—The etiology and pathogenesis are connected with diabetes and vascular disease in some unexplained manner. In young diabetics it usually takes some 15 or 20 years of the disease well or poorly controlled to culminate in the general vascular degeneration of which the renal arteriolar and glomerular changes are only a part. In older diabetics the exact duration of diabetes before the onset of renal involvement is undetermined and the frequency of coincidental hypertension increases the difficulty of the estimation. The glomerular hyaline ball degeneration of intercapillary glomerulosclerosis is directly diabetic in origin. Once the glomerular lesions develop the stage is set for proteinuria, lipoid degeneration of tubules and increasing renal insufficiency as glomeruli become obliterated and tubules atrophy. Desquamation of tubular epithelium laden with doubly refractile lipoid or cholesterol esters furnishes a valuable diagnostic criterion in the urinary sediment. Renal vascular changes are sufficient to produce hypertension.

*Symptoms and Course*.—In a known diabetic without a history of acute glomerulonephritis or abnormal hematuria the classical syndrome consists of marked proteinuria, hypoalbuminemia and hypercholesterolemia, moderate hypertension, diabetic retinopathy, nephrotic edema and fair or normal renal function. Actually this is a relatively rare combination of findings. More commonly the diabetic with hypertension and obvious retinopathy or peripheral vascular disease has proteinuria and edema not attributable to congestive heart failure or has proteinuria, anemia and renal insufficiency or uremia not explained by the common forms of bilateral renal disease. Other variations occur, including the absence of hypertension or of retinopathy. Even in patients with considerable proteinuria hypoalbuminemia is not a constant feature. The earliest signs of Kimmelstiel-Wilson disease are still unknown. Among older patients the diabetes may be latent and the renal disease suspected only because of the urinary findings. In these cases glucose tolerance tests are necessary for diagnosis of diabetes. On the other hand hypertensive and arteriosclerotic heart disease with congestive failure in older diabetics may effectively mask the diabetic glomerulosclerosis.

The course of the disease is usually only a matter of a few years. It progresses inevitably to uremia although cardiac, cerebral or peripheral vascular complications may be the immediate cause of death.

*Diagnosis*.—Diagnosis of Kimmelstiel-Wilson disease is relatively easy in the older age groups: proteinuria and edema appear in a diabetic without evidence of congestive heart failure or a valid background for amyloidosis (chronic suppurative tuberculosis, bronchiectasis or rheumatoid arthritis). The finding of doubly refractile lipoid cells and casts in the urine is virtually diagnostic. In dealing with the younger diabetics, usually in the third or fourth decade of life, many with histories of repeated respiratory or skin infection, the possibility of chronic glomerulonephritis must always be borne in mind. Active glomerulonephritis usually causes more hematuria than is indicated by the occasional red cells seen in the urine in diabetic glomerulosclerosis and the association of a normal urea clearance with chronic hypertension and urinary changes is most improbable in chronic glomerulonephritis but is possible in the earlier stages of diabetic glomerulosclerosis. Amyloidosis is also to be considered in younger diabetics but will present no serious problem if typically developed. The rare association of diffuse allergic vascular disease or visceral lupus erythematosus with diabetes may produce confusing renal findings but the general clinical features will ordinarily clarify the diagnosis. Diabetic glomerulosclerosis may be combined with pyelonephritis, necrotizing renal papillitis or infection of the lower urinary tract. In this last the characteristic urinary sediment changes of the Kimmelstiel-Wilson disease may be completely obscured by the pyuria and alkaline reaction of the urine. Even here the presence of noncardiac edema

the mechanism of hypertension in the middle and older age groups. Apart from the high incidence at autopsy of renal arterio- and arteriolosclerosis in victims of hypertensive disease and the much lower incidence in *renal biopsies obtained during dorsolumbar* sympathectomy on subjects with less advanced hypertension, nothing definite is known about the exact relationship between hypertension and renal vascular changes in man. The arteriolosclerosis of the afferent glomerular arterioles extends into the intraglomerular capillary branches, leading to gradual thickening and hyalinization of the walls and obliteration of vascular channels. Ultimately, the entire glomerulus becomes hyalinized, sclerotic and useless, the corresponding tubule is deprived of blood supply and atrophies. The process may be very gradual in a few cases, however, it may be accelerated to a necrotizing arteriolitis and glomerulitis with microscopic infarction of nephrons and rapid destruction of kidney tissue and function. This process often affects simultaneously small vessels elsewhere in the body (*e g*, in the brain, in the adrenals, the pancreas, the gastrointestinal tract and the retina). This is malignant nephrosclerosis pathologically or malignant hypertension clinically, but the two terms are far from synonymous since they are based on different sets of criteria.

*Symptoms and Course* —The *symptoms* are those of the hypertensive syndrome. The urinary findings are these: proteinuria mild to moderate, a few if any erythrocytes (except in arteriolonecrosis), some hyaline and granular casts in the sediment. The maximal specific gravity of the urine may be normal at first (though ordinarily somewhat reduced) but eventually becomes fixed at the isosthenuric level. There is no edema until cardiac failure occurs. Renal functional impairment indicative of diminished tubular mass and excretory ability and reduced renal blood flow with relatively well preserved glomerular filtration (hence an increased filtration fraction) are usually found by the special clearance tests at this stage. The urea clearance may be within lower normal range, unlike the situation in chronic hypertensive glomerulonephritis. Left-ventricular enlargement, left-ventricular-strain pattern in the ECG, and signs of hypertensive retinopathy are ordinarily observed by the time the renal signs of hypertensive disease appear. Cerebral vascular damage of varying degree may be found at this stage. The increasing renal insufficiency may terminate in uremia, but this occurs in only 10 or 15 per cent of the cases, the rest of the hypertensives succumb chiefly to cardiac failure, coronary or cerebral accident, or intercurrent infection.

*Diagnosis* —The diagnosis of nephrosclerosis is readily made when chronic hypertensive disease and urinary changes are found. Chronic pyelonephritis with hypertension can usually be distinguished from nephrosclerosis from the history in the former of urinary tract infection, obstruction, pyuria and bacteriuria, and pyelographic abnormality. In some cases, however, no positive criteria may be available, although renal function is likely to be more impaired in pyelonephritis than in nephrosclerosis. It is important, particularly in younger persons with severe hypertension and retinopathy, to consider the possibility of unilateral atrophic pyelonephritis. Pheochromocytoma with nonparoxysmal hypertension and urinary abnormality is a rare disease but must be kept in mind and tested for by means of benzodioxane. The Cushing syndrome will present other obvious features besides hypertension, proteinuria and renal impairment. However, obesity and essential hypertension are often combined and even diabetes and amenorrhea may be thrown in for good measure without necessarily implicating the adrenal hyperfunction of the *Cushing syndrome*. Polycystic kidneys when not readily palpable may cause confusion in diagnosis.

*Treatment* —Treatment of arteriolar glomerulosclerosis consists in the management of hypertension and renal dysfunction. The latter requires no special care until considerable renal insufficiency has developed. In most cases the real therapeutic problem will be cardiac or cerebral in origin.

## DIABETIC GLOMERULOSCLEROSIS

Diabetic glomerulosclerosis or the intercapillary glomerulosclerosis of Kimmelstiel

sive mechanism This however is unusual in amyloidosis the cachexia and the concurrent involvement of the liver and the adrenals are much more likely to be associated with arterial hypotension Once heavy proteinuria has set in the rest of the nephrotic syndrome is a logical sequence in amyloid glomerulonephrosis It is modified however, by the nutritional and metabolic aberrations associated with the primary disease Involvement of the heart muscle in primary amyloidosis may cause cardiac failure

*Symptoms and Course* —Amyloid glomerulonephrosis may be characterized by proteinuria and cylindruria a complete nephrotic syndrome, a mixture of nephrotic and uremic manifestations or undiluted asthenic uremia The renal symptoms may be confused with clinical expressions of the underlying disease or with the effects of amyloid deposition in liver adrenals myocardium gastrointestinal tract bone marrow and elsewhere Weakness emaciation hypotension anemia pigmentation and gastrointestinal disturbances are common in well-established amyloid nephrosis Anorexia and a reduced salt intake will limit the amount of edema Hypercholesterolemia is often absent owing to cachexia caused by the underlying disease A positive result in the Congo red test will be obtained if there is general amyloidosis the result may be doubtful if the kidneys are chiefly involved or the amyloid is atypical The urine may contain considerable serum globulin in addition to serum albumin In cases with more tubular than glomerular dysfunction no edema is observed On the contrary the salt losing type of renal disease may develop with electrolyte depletion and dehydration and mimic the syndrome of adrenal cortical insufficiency

The *course* of amyloid nephrosis depends on the degree of renal functional impairment at the time of diagnosis and on the nature and activity of the underlying disease Proteinuria may exist for some years before more serious signs appear Once renal insufficiency is obvious the disease lasts about two years or less unless a striking improvement in the causative condition can be effected The *prognosis* in renal amyloidosis is poor once the disease is fully established

*Diagnosis* —Diagnosis of renal amyloidosis is easy in the average case in a child or young adult with a disease furnishing a background for amyloidosis Chronic glomerulonephritis is readily excluded by the absence of significant hematuria and hypertension and by the presence of proteinuria out of all proportion to the number of casts or epithelial cells In children orthostatic or postural proteinuria must be considered in the differential diagnosis of early stages of amyloid glomerulonephrosis In older patients especially those with arteriosclerotic heart disease and congestive failure the finding of doubly refractile lipoid cells or casts in the urine sediment will be diagnostically helpful if diabetes can be excluded The Congo red test is of value in diagnosing renal amyloidosis in older persons In general, differential diagnosis of the renal involvement is facilitated if there is reason to suspect amyloid deposition in the liver and spleen Biopsy of the liver often establishes the diagnosis Biopsy of the gums may reveal amyloid in a few cases

*Treatment* —Treatment consists primarily in eradicating or sterilizing chronic foci of suppuration in the lungs the bones the joints and elsewhere The maintenance of optimal nutrition on diets high in protein and in vitamins and the control of anemia also help prevent amyloid formation and deposition

As for *symptomatic treatment* the usual measures for control of edema hypoproteinemia and azotemia are instituted

Due allowance is made for the general nutritional status which is often quite poor It has been held that the parenteral administration of large amounts of liver extract preferrably in the crude form in addition to the use of diets high in protein has cleared up amyloidosis including the renal deposits It is certainly established that the liver and spleen can reabsorb amyloid completely under proper conditions Whether this also holds for the kidney is not clear

## LIPOID GLOMERULONEPHROSIS

*Lipoid glomerulonephrosis* or "genuine" lipoid nephrosis is a disease of infants and

should lead the physician to suspect glomerulosclerosis.

*Treatment.*—Treatment of glomerulosclerosis consists in the prevention of diabetes mellitus, wherever possible, through the control of obesity and other predisposing factors.

*Symptomatic treatment* of diabetic glomerulosclerosis includes the standard treatment of diabetes mellitus and the individual symptoms of the renal complication. In regard to the diabetes, it must be noted that increasing renal impairment tends to reduce glycosuria by diminished glomerular filtration. Hence, the insulin requirement becomes smaller and hyperglycemia is common without glycosuria. Attempts to keep the blood glucose in the normal range by extra insulin doses are likely to cause serious hypoglycemic reactions and should be discouraged. In some patients no insulin need be given. The absence of glycosuria does not mean that ketosis and ketonuria are absent. They should always be tested for. The diet is kept low in salt, as for cardiac cases, if the patient has significant edema. The normal protein intake in the diabetic diet is adequate to cover the proteinuria in most cases of diabetic glomerulosclerosis. In those with 20 or more grams of protein in the 24 hour urine, supplementary dietary protein is indicated. However, patients with glomerulosclerosis seem to maintain their plasma-albumin levels with less difficulty than the nephrotic glomerulonephritic patient. When renal impairment reaches the point of considerable nonprotein nitrogen retention, appropriate reduction in protein intake and increase in fluids intake are indicated. Cardiac failure is treated as usual. The use of mercurial diuretics should be avoided unless the level of renal function is more than 30 per cent by the urea clearance test and the patient responds to a test dose. The use of ammonium chloride or other acid forming salts as diuretic adjuvants must also be avoided if there is considerable renal insufficiency. The mobilization of edema in diabetic glomerulosclerosis may be most difficult because of the combination of four factors antagonistic to diuresis—renal excretory failure, cardiac insufficiency, anemia, and hypoproteinemia. Mechanical removal of edema fluid from body cavities and subcutaneous tissues is employed where other measures fail. The liability of diabetics to urinary-tract infections makes it imperative to culture the urine frequently and to use antibiotics liberally. Insulin resistance may be an aggravating factor in rare cases.

## GLOMERULONEPHROSIS

The glomerulonephroses are amyloid nephrosis, lipoid nephrosis, and the nephrosis of pregnancy.

### *AMYLOID GLOMERULONEPHROSIS*

Amyloid glomerulonephrosis is usually part of general amyloidosis, whether secondary or primary in type, although it may occasionally represent the major amyloid deposit in the body. Its incidence is diminishing rapidly because of better surgical treatment of chronic suppuration in bones and lungs and antibiotic therapy of infections. The cortisone and ACTH treatment of rheumatoid arthritis may, in the future, still further reduce the incidence of renal amyloidosis.

*Etiology and Pathogenesis.*—The etiology and pathogenesis of amyloid glomerulonephrosis are part of the unsolved problem of amyloidosis in general. The role of hyperglobulinemia in producing amyloidosis is unproven and there are striking discrepancies in the alleged association. In secondary amyloidosis, related to chronic suppuration, rheumatoid arthritis and the lymphomas (Hodgkin's disease and multiple myeloma), the kidney is regularly involved. The amyloid is deposited in the glomeruli and the membrana propria of the tubules. The glomerular permeability for serum protein is increased; later filtration is reduced by the encroachment of the amyloid on the capillaries. Eventually complete obstruction to blood flow occurs; hyaline fibrosis follows. Corresponding tubular ischemia, degeneration, atrophy, and replacement fibrosis lead to increasing tubular functional impairment. Among older patients, though seldom among younger ones, without a wasting disease, sufficient renal vascular involvement may occur to set off the humoral hyperten-

sive mechanism This, however, is unusual in amyloidosis the cachexia and the concurrent involvement of the liver and the adrenals are much more likely to be associated with arterial hypotension Once heavy proteinuria has set in the rest of the nephrotic syndrome is a logical sequence in amyloid glomerulonephrosis It is modified however by the nutritional and metabolic aberrations associated with the primary disease Involvement of the heart muscle in primary amyloidosis may cause cardiac failure

*Symptoms and Course* —Amyloid glomerulonephrosis may be characterized by proteinuria and cylindruria a complete nephrotic syndrome a mixture of nephrotic and uremic manifestations or undiluted asthenic uremia The renal symptoms may be confused with clinical expressions of the underlying disease or with the effects of amyloid deposition in liver adrenals myocardium gastrointestinal tract bone marrow and elsewhere Weakness emaciation hypotension anemia pigmentation and gastrointestinal disturbances are common in well established amyloid nephrosis Anorexia and a reduced salt intake will limit the amount of edema Hypercholesterolemia is often absent owing to cachexia caused by the underlying disease A positive result in the Congo red test will be obtained if there is general amyloidosis the result may be doubtful if the kidneys are chiefly involved or the amyloid is atypical The urine may contain considerable serum globulin in addition to serum albumin In cases with more tubular than glomerular dysfunction no edema is observed On the contrary the salt losing type of renal disease may develop with electrolyte depletion and dehydration and mimic the syndrome of adrenal cortical insufficiency

The *course* of amyloid nephrosis depends on the degree of renal functional impairment at the time of diagnosis and on the nature and activity of the underlying disease Proteinuria may exist for some years before more serious signs appear Once renal insufficiency is obvious the disease lasts about two years or less unless a striking improvement in the causative condition can be effected The *prognosis* in renal amyloidosis is poor once the disease is fully established

*Diagnosis* —Diagnosis of renal amyloidosis is easy in the average case in a child or young adult with a disease furnishing a background for amyloidosis Chronic glomerulonephritis is readily excluded by the absence of significant hematuria and hypertension and by the presence of proteinuria out of all proportion to the number of casts or epithelial cells In children orthostatic or postural proteinuria must be considered in the differential diagnosis of early stages of amyloid glomerulonephrosis In older patients, especially those with arteriosclerotic heart disease and congestive failure the finding of doubly refractile lipoid cells or casts in the urine sediment will be diagnostically helpful if diabetes can be excluded The Congo red test is of value in diagnosing renal amyloidosis in older persons In general differential diagnosis of the renal involvement is facilitated if there is reason to suspect amyloid deposition in the liver and spleen Biopsy of the liver often establishes the diagnosis Biopsy of the gums may reveal amyloid in a few cases

*Treatment* —Treatment consists primarily in eradicating or sterilizing chronic foci of suppuration in the lungs the bones the joints and elsewhere The maintenance of optimal nutrition on diets high in protein and in vitamins and the control of anemia also help prevent amyloid formation and deposition

As for *symptomatic treatment* the usual measures for control of edema hypoproteinemia and azotemia are instituted

Due allowance is made for the general nutritional status which is often quite poor It has been held that the parenteral administration of large amounts of liver extract preferrably in the crude form in addition to the use of diets high in protein has cleared up amyloidosis including the renal deposits It is certainly established that the liver and spleen can reabsorb amyloid completely under proper conditions Whether this also holds for the kidney is not clear

## LIPOID GLOMERULONEPHROSIS

*Lipoid glomerulonephrosis* or genuine lipoid nephrosis is a disease of infants and

young children characterized by the nephrotic syndrome without any of the other signs of glomerulonephritis Remissions and relapses are common but complete cure occurs in about half the cases even after years of the disease Occasionally, the disease is active for more than a decade and results in renal insufficiency secondary to gradual tubular atrophy and replacement fibrosis Before the days of chemotherapy and antibiotics death often resulted from intercurrent infection particularly erysipelas or cellulitis of the edematous skin peritonitis in the presence of ascites and nutritional crises associated with hypoaminoacidemia and liver dysfunction Curiously enough some of the most striking remissions and permanent cures in cases of this disease have followed acute infections of all sorts especially measles *This has actually led to the deliberate induction of measles in nephrotic children with very stubborn edema and ascites*

*Etiology and Pathogenesis* —To those who believe that there is no such thing as pure or genuine lipoid nephrosis that it is always a variant of mild chronic glomerulonephritis in which the inflammatory element is at a minimum the etiology is clear and the pathogenesis similar to that of the parent disease However, the existence of a clinical and pathological complex of a specific type is well established There are two theories the first that the abnormal glomerular permeability to serum albumin is the expression of a degenerative process limited initially at least to the kidney the second that the renal changes are merely part of a general metabolic disorder involving protein synthesis and related processes According to the first theory proteinuria leads to reduction in the serum proteins nephrotic edema tissue protein breakdown lipemia susceptibility to infections and other features of true nephrosis According to the second theory, the edema and the hypoalbuminemia are not directly related to the proteinuria but, respectively to the altered metabolic and sodium reabsorptive activity of the renal tubules and the abnormal protein synthesis The two views are not irreconcilable The actual etiology of the glomerular change is not known it is not so clearly related to streptococcal or other infection as is glomerulonephritis, but there seems to be some relationship There is some clinical evidence to support the view that certain drugs, like tridione and sensitizing agents like poison oak, may be causal factors The tubular degeneration so striking in the pathology of the kidney in nephrosis is presumably largely the effect of the accumulation of lipids (cholesterol esters especially) in the epithelium of the convoluted tubules These deposits apparently derive to a considerable extent from plasma material filtered through the damaged glomeruli *The functional capacity of the* glomeruli and the tubules remains strikingly unimpaired, except for the reduced excretion of salt and water Even this is simply an expression of excellent reabsorptive activity

*Symptoms and Course* —The symptoms and course are very much like those of nephrotic nephritis, except for the more insidious onset and more stubborn course Generalized edema of the waxy type, effusions into body cavities and tissue wasting masked by the inflated appearance of the nephrotic child, form a striking and unforgettable picture Anorexia, vomiting and diarrhea of a watery type are common in the severely edematous patient Secondary anemia is to be expected as are vitamin deficiencies The tense water laden skin is easily broken and subject to cellulitis Edema of the external genitalia may interfere with urination Swelling of the eyelids may be a source of annoyance and conjunctival edema may result in irritation The edema is usually soft, freely movable and non tender It affects the face the scalp and the arms Dehydration due to anorexia and gastrointestinal disturbance may be combined with the edema This may lead to cerebral symptoms a shocklike state and prerenal azotemia with variable electrolyte disturbances Ordinarily in the nephrotic child the serum sodium is low normal the serum CO reduced and the chloride elevated

The *urine* is often highly concentrated and alkaline except during diuresis Protein casts and epithelium including many doubly refractile lipoid cells also found in casts are present in the urine The

protein concentration in the urine may reach 4 or 5 per cent and the 24 hour loss often reaches 10 or 20 grams about 90 per cent in the form of albumin Fine chemical, electrophoretic and immunologic distinctions between the serum and urinary proteins of nephrosis and the normal serum proteins can be demonstrated but their exact significance is unknown The changes may represent basic alteration in the protein regenerating mechanism or the result of rapid loss and rapid regeneration and lack of time for complete maturation of the various fractions The latter possibility is supported by the fact that the serum proteins rapidly return to normal whenever a remission in the disease is accompanied by a striking reduction in or cessation of proteinuria That the lipemia and the hypercholesterolemia of nephrosis should be accompanied by a rise in the beta globulin fraction of the serum is not surprising Perhaps the low resistance to infection is in keeping with the usually low level of gamma globulin in nephrosis

The results of the ordinary *renal function tests* are normal in nephrosis but water excretion in the dilution test is considerably delayed The urea nitrogen in the blood is normal but varies with the level of protein in the diet and the fluid intake The glomerular filtration rate is not only normal but often considerably elevated as is the renal blood flow Tubular maximal excretory capacity for diodrast and p aminohippurate may also be increased markedly The explanation for these remarkable changes is not apparent These supernormal values are readily induced in young nephrotic children by diets high in protein All these functional changes are in a different direction for those seen in nephrotic glomerulonephritis There is some evidence of increased antidiuretic material in the urine this suggests an excess of hormonal activity on the distal tubule

The *course* of lipoid glomerulonephrosis is characteristically one of remissions and relapses After months of stationary or increasing edema—edema resistant to all ordinary measures and accompanied by heavy proteinuria serum albumin levels often below 1 5 grams per cent and blood protein levels well below 4 per cent—sudden diuresis may set in spontaneously Luetscher has found a significant increase in plasma volume an early signal of this diuresis An intercurrent infection of almost any type may be associated with a relapse into the edematous state or with a sharp decrease in the proteinuria and a rapid disappearance of the edema followed by a gradual rise in the serum proteins The most dramatic remissions seem to have occurred at the height of the eruption of measles In fact a number of authentic cures of nephrosis have been reported after this infection In most cases however relapse takes place after a few weeks or months Massive edema effusion of fluid into the body cavities malnutrition due to anorexia tissue wastage and marked proteinuria render the nephrotic child unusually susceptible to pneumococcal streptococcal and other infections of the respiratory tract the skin and the peritoneum In the presulfonamide days such infections often proved fatal though renal function was still excellent Pyrexia and abdominal pain tenderness and rigidity should arouse the suspicion of peritonitis (usually pneumococcal) The peritoneal fluid should be aspirated and smears and cultures of it made Sudden fever prostration listlessness pallor nausea severe abdominal or flank pain with distention and rapid grunting respiration may indicate a *nephrotic crisis* of metabolic origin related to a low plasma amino acid level (less than 2 5 mg per 100 cc by the ninhydrin method) of sudden or gradual development These attacks last only from 12 to 48 hours unless complicated by infection

*Differential Diagnosis* —Lipoid glomerulonephrosis is chiefly to be distinguished from nephrotic glomerulonephritis The absence of hematuria in highly concentrated acid urine is the most differential sign

Any elevation of blood pressure or sign of persistent renal functional impairment not due to pre renal factors should make one very skeptical of a diagnosis of nephrosis Amyloid nephrosis is usually readily excluded by its background of suppurative disease and evidence of hepatic and splenic

young children characterized by the nephrotic syndrome without any of the other signs of glomerulonephritis. Remissions and relapses are common, but complete cure occurs in about half the cases even after years of the disease. Occasionally, the disease is active for more than a decade and results in renal insufficiency secondary to gradual tubular atrophy and replacement fibrosis. Before the days of chemotherapy and antibiotics, death often resulted from intercurrent infection, particularly erysipelas or cellulitis of the edematous skin, peritonitis *in the presence of ascites*, and *nutritional* crises associated with hypoaminoacidemia and liver dysfunction. Curiously enough, some of the most striking remissions and permanent cures in cases of this disease have followed acute infections of all sorts, especially measles. This has actually led to the deliberate induction of measles in nephrotic children with very stubborn edema and ascites.

*Etiology and Pathogenesis.*—To those who believe that there is no such thing as pure or genuine lipoid nephrosis, that it is always a variant of mild chronic glomerulonephritis in which the inflammatory element is at a minimum, the etiology is clear and the pathogenesis similar to that of the parent disease. However, the existence of a clinical and pathological complex of a specific type is well established. There are two theories: the first, that the abnormal glomerular permeability to serum albumin is the expression of a degenerative process limited, initially at least, to the kidney; the second, that the renal changes are merely part of a general metabolic disorder involving protein synthesis and related processes. According to the first theory, proteinuria leads to reduction in the serum proteins, nephrotic edema, tissue protein breakdown, lipemia, susceptibility to infections and other features of true nephrosis. According to the second theory, the *edema and the hypoalbuminemia* are *not* directly related to the proteinuria but, respectively, to the altered metabolic and sodium reabsorptive activity of the renal tubules and the abnormal protein synthesis. The two views are not irreconcilable. The actual etiology of the glomerular change is not known. It is not so clearly related to streptococcal or other infection as is glomerulonephritis, but there seems to be some relationship. There is some clinical evidence to support the view *that certain drugs, like tridione, and sensitizing* agents, like poison oak, may be causal factors. The tubular degeneration so striking in the pathology of the kidney in nephrosis is presumably largely the effect of the accumulation of lipids (cholesterol esters especially) in the epithelium of the convoluted tubules. These deposits apparently derive to a considerable extent from plasma *material filtered through the damaged* glomeruli. The functional capacity of the glomeruli and the tubules remains strikingly unimpaired, except for the reduced excretion of salt and water. Even this is simply an expression of excellent reabsorptive activity.

*Symptoms and Course.*—The symptoms and course are very much like those of nephrotic nephritis, except for the more *insidious onset and more stubborn course.* Generalized edema of the waxy type, effusions into body cavities and tissue wasting masked by the inflated appearance of the nephrotic child form a striking and unforgettable picture. Anorexia, vomiting, and diarrhea of a watery type are common in the severely edematous patient. Secondary anemia is to be expected, as are vitamin deficiencies. The tense, water-laden skin is easily broken and subject to cellulitis. Edema of the external genitalia may interfere with urination. Swelling of the eyelids may be a source of annoyance, and conjunctival edema may result in irritation. The edema is usually soft, freely movable and non-tender. It affects the face, the scalp and the arms. Dehydration due to anorexia and gastrointestinal disturbance may be combined with the edema. This may lead to cerebral symptoms, a shocklike state and pre-renal azotemia with variable electrolyte disturbances. Ordinarily in the nephrotic child the serum sodium is low normal, the serum $CO_2$ reduced, and the chloride elevated.

The *urine* is often highly concentrated and alkaline except during diuresis. Protein, casts and *epithelium*, including many doubly refractile lipoid cells, also found in casts, are present in the urine. The

cence Or the fever may be irregularly continuous with severe prostration stupor or mental confusion Dehydration may develop rapidly in children especially when diarrhea is one of the early symptoms Abdominal distention with other signs of paralytic ileus may occur There is often marked costovertebral tenderness or sensitivity to percussion over this area It may be much more marked on one side than on the other The kidneys may be palpable enlarged and tender Stretching of the iliopsoas muscle may aggravate the pain in the flank or abdomen A moderate leukocytosis with increase in polymorphonuclears and a shift to the left is common Anemia may develop rapidly even to the point of slight icterus In the severe types signs of general toxemia are evident Bacteriemia is often found when blood is taken for culture from a patient undergoing a chill Enlargement and tenderness over the liver and spleen result The chemical blood changes usually reflect the increased protein catabolism dehydration and a variable degree of renal impairment

The *urine* early is concentrated and usually turbid or cloudy The reaction is usually acid with E coli and streptococcal infections but is alkaline in infections due to urea-splitting staphylococci B proteus and related bacteria It shows moderate protein content a purulent sediment and often bacteria on direct smear A variable number of erythrocytes is also present but not in cast form Gross hematuria may be seen The leukocytes are found typically in clumps and sometimes massed in casts Granular and epithelial casts may also be present However there are cases in which for a few days there may be very little pus in the urine this is due either to failure of the interstitial exudates to extend into the renal excretory ducts or what is more serious to obstruction of the renal pelvis or ureter by a plug of coagulated pus Culture of the urine will reveal the offending bacteria and is an essential part of the examination of the patient

The *course* of an acute pyelonephritis is ordinarily self limited to a few days or one or two weeks even without specific treatment provided there is no serious obstruction of the urinary tract If the patient stays in bed and is able to retain enough fluids to irrigate his urinary channels the acute infection sooner or later subsides and there may be no residual damage nor may there be recurrence of the disease However retention of purulent exudate in the renal pelvis may lead rapidly to a pyonephrosis or generalized septicemia In some instances the renal parenchyma is seeded with numerous miliary abscesses and grossly purulent infiltrates In these cases the clinical picture is a combination of severe infection and toxemia and increasing renal insufficiency This is particularly likely to occur in ascending infections from obstructed or paralytic bladders but may also result from hematogenous staphylococcal infection in patients with furuncles or osteomyelitis Extension of suppuration through the capsule of the kidney may result in perinephritic abscess Septic emboli from infected renal veins will lodge in the lungs to produce suppurative pneumonitis or infarct formation

*Diagnosis* —There is usually no difficulty in diagnosis of acute pyelonephritis if one remembers to consider this condition in any patient of any age with otherwise unexplained fever abdominal symptoms or urinary-tract signs In infants and children it is one of the major causes of febrile infection Any patient with known urolithiasis urinary stricture enlarged prostate or any congenital anomaly of the urinary tract capable of causing obstruction is potentially a candidate for acute pyelonephritis The differential diagnosis from other common causes of fever and abdominal pain is based largely on the typical urinary findings including the important urine cultures Intravenous pyelography may be very useful in disclosing the underlying obstructive lesion especially in cases with unilateral pain and upper abdominal tenderness when distinction from acute gall bladder disease may be difficult Differentiation from acute glomerulonephritis is ordinarily easy because of the absence of edema hypertension and erythrocyte casts However since in glomerulonephritis there may be little hypertension or edema and the urine may contain leukocytes in addition to the other findings

until recovery has occurred. Future pregnancies are not contraindicated if renal function, the urine, and the blood pressure remain normal.

## PYELONEPHRITIS OR PYOGENIC INFECTIONS OF THE KIDNEYS

Pyogenic renal infections constitute the largest and most important group of organic renal diseases. Fortunately, they are the most susceptible to specific therapy.

### ACUTE PYELONEPHRITIS

Acute pyelonephritis is the most common of the diffuse renal diseases. It is caused by a variety of pyogenic bacteria. It often reveals an underlying urinary tract obstruction or anomaly.

*Etiology and Pathogenesis.*—Any microorganism capable of producing suppurative inflammation may lodge in the kidneys and initiate acute pyelonephritis. The bacteria usually responsible for pyelonephritis are the gram negative bacilli of the E. coli group, A. aerogenes, B. proteus, Pseudomonas aeruginosa, and various enterococci. Staphylococci may also be involved. Mixed infections are common in recurrent or chronic cases. The tubercle bacillus is an important cause of specific pyelonephritis and must always be considered when urinary tract infection exists in the presence of urine sterile for ordinary pathogens. Organisms like E. typhosa may pass through the kidney into the urine without producing any renal inflammation of note.

The theory of ascending infection of the renal pelvis and parenchyma is apparently supported by the incidence of pyelitis or pyelonephritis after urethritis, prostatitis and cystitis, especially when instrumental examination or urethral catheterization has been carried out. However, even in these cases there is good reason to believe that traumatic bacteriemia has occurred. The influence of pregnancy in producing hormonal and mechanical stasis in the ureter predisposes to pyelonephritis.

Microorganisms ordinarily reach the kidneys via the circulation, multiply in the interstitial tissue around the glomeruli and tubules, and set up reactions varying from inflammatory edema and leukocytic infiltration to massive suppuration and extension of inflammation to adjacent structures. Secondary invasion of renal venous channels and lymphatics spread the infection throughout the circulation. Less frequently bacteria invade the kidney along the lymphatics from the lower urinary or adjacent bowel tract or, in neurogenic bladders, by direct reflux of infected bladder urine. The suppurative process in the kidney usually breaks into the collecting ducts and involves the renal pelvis—pyelitis is nearly always part of a pyelonephritis—and purulent material may obstruct the calyces or ureter to produce serious consequences. The interstitial inflammation extends to the blood vessels and leads to thrombophlebitis and arteritis. The latter may be responsible not only for ischemic necrosis or atrophy of renal parenchyma but, under appropriate circumstances, for the release of the Goldblatt pressor mechanism to produce an intermittent, chronic or accelerated malignant hypertension. Varying degrees of renal insufficiency result from these processes but this feature of pyelonephritis is usually not important until a long period has elapsed. There are infrequent instances of acute interstitial pyelonephritis with severe edema of the kidneys, high intrarenal tension and oliguria sufficient to produce acute uremia. The inflammatory process may be asymmetrical and productive of unilateral atrophy.

*Symptoms and Course.*—In children and young adults acute pyelonephritis may begin explosively with chill, high fever, abdominal or flank pain, nausea, vomiting, urgent or burning urination. This syndrome may follow an upper respiratory infection, complicate the latter half of pregnancy, or supplement an attack of renal colic. It may follow diagnostic or therapeutic instrumentation or catheterization of the lower urinary tract. In older patients, particularly males with hypertrophied prostates, the onset may not be quite so dramatic, the temperature may be lower and the pain over the kidney region less severe. In severe infections chills and fever may recur daily or oftener with wide swings in temperature and drenching sweats on deferves-

tion of renal parenchyma is favored by the underlying obstructive lesions and later, the scars and deformities produced by the inflammation itself. Gradually, as more and more tubules are destroyed, replacement fibrosis occurs; this in turn strangles the preserved colloid-filled tubules. The glomeruli tend to hold out longer but ultimately succumb to the fibrosis around them. In addition, obliterative endarteritis adds to parenchymal ischemia and atrophy and may be associated with severe hypertension. This entire process may be uniformly distributed throughout both kidneys and lead to smooth shrinkage, or it may be focally expressed in chronic infiltrates and scars with intervening normal or hypertrophied parenchyma. Often, however, asymmetrical inflammation and atrophy occurs; in selected instances these may be responsible for a hypertensive syndrome including the malignant phase. Secondary hypertensive vascular changes may occur in the larger, better-functioning kidney. Pelvic and calyceal scarring with dilatation proximal to obstruction is responsible for pyelographic changes helpful in diagnosis.

*Symptoms and Course.*—Chronic pyelonephritis may run a variety of courses. Some patients, after a severe first attack, continue to have periods of low grade fever, general malaise, fatigue, unilateral or bilateral lumbar pain, gastrointestinal disturbance, mild secondary anemia, poor tolerance for exercise, and other nondescript symptoms. These may last for weeks or months, clear up and recur, often with some frequency or burning on urination. The urine may be grossly turbid or muddy and malodorous. Other patients go for months or years without subjective symptoms but occasionally experience a few days of fever and dysuria, with or without pain over one or both kidneys. The course may be completely asymptomatic for a long time except for some anemia and borderline rises in blood pressure. Prolonged and severe or accelerated hypertension may develop. In patients with kidney stones, attacks of colic and hematuria may precede recurrence of active symptoms of pyelonephritis and occasionally precipitate a fulminating infection with severe loin pain, chills, high fever, general toxemia and prostration. Acute pyonephrosis or multiple miliary abscesses are found in this condition, which is very dangerous when both kidneys are affected. In a small number of young subjects with unilateral atrophic pyelonephritis, a clinical syndrome develops with severe hypertension including the retinopathy of the malignant phase of hypertension, left ventricular hypertrophy and attacks of acute left-ventricular failure, severe tension headaches, dizziness, vomiting and even convulsive encephalopathy. Urinary tract infection may not be evident or suspected in this group until complete urographic and functional studies of each kidney are carried out. In chronic pyelonephritis the symptoms of an underlying obstructive lesion may confuse or dominate the picture.

In most patients with chronic pyelonephritis there is some degree of tubular impairment manifested by inability to concentrate the urine maximally. The urea nitrogen level of the blood may be little elevated in the earlier stages. Some hypochromic anemia is usually seen. Edema never occurs except as a sign of heart failure in the hypertensive patient or in the very late stages of the disease when uremia is already at hand. During the gradual development of renal insufficiency, considerable acidosis may supervene without affecting the patient remarkably apart from dyspnea on exertion. Occasionally the tubular impairment leads to a salt-losing disturbance which may mimic the dehydration and salt depletion of Addison's disease. In patients with calculous pyelonephritis secondary to hyperparathyroidism, the blood chemical and bony changes of the primary disease will be detectable, the former modified by renal insufficiency and its phosphate retention.

*Diagnosis.*—When the patient is first seen during an acute recurrence of chronic pyelonephritis, it may be difficult, without an adequate history, to distinguish it from an initial acute attack. Impaired renal function persisting after the acute symptoms have subsided speaks for the chronic renal involvement. Roentgen findings of irregularities, distortion, dilatation or constriction of renal pelves or calyces, often asym-

cultures of the urine are very helpful in some cases Also in acute glomerulonephritis which is usually produced by the beta hemolytic streptococcus, the antistreptolysin *titer in the serum will be high* Acute cystitis is usually distinguished from pyelonephritis by the frequency of urination, pain at beginning and end of urination, milder general symptoms and terminal hematuria Ordinarily, there is suprapubic or rectal tenderness but no lumbar tenderness Urinary casts are absent and the proteinuria is more in proportion to the hematuria and pyuria "Pyelitis" is not to be differentiated from what it really is—pyelonephritis

*Treatment* —The treatment of acute pyelonephritis begins with relief of any urinary-tract obstruction In children, the possibility of congenital strictures, valves aberrant renal vessels, malposition reduplication and other anomalies must be considered, *once the acute infection has been* brought under control

*Specific antibiotic treatment* will vary with the results of urine cultures While awaiting their outcome a combination of penicillin and sulfa or streptomycin or aureomycin, in full dosage is given for the first few days The sensitivity of urinary bacteria should be tested if there is any question about the clinical response Aureomycin or chloramphenicol may have to be used for relatively resistant gram negative bacilli To promote a high concentration of antibiotic in the urine, the fluid intake should not be forced too high early in the course unless there is considerable dehydration Treatment with antibiotics should be continued until pyuria has ceased and repeated urine cultures at intervals of several days or a week show no growth of the offending bacteria

*Symptomatic therapy* includes maintenance of adequate hydration prescription of a light diet (or parenteral feeding if necessary) the use of analgesics and sedation as indicated, the administration of supportive blood transfusions for anemia and good *nursing* during the recurrent chills, fever and sweats The bowels should be kept open with mild laxatives or small enemas Tympanites or ileus may require small doses of prostigmine Excessive vomiting may be *stopped by gastric intubation and aspiration* Careful replacement of fluids lost is necessary *to prevent dehydration and electrolyte im*balance This is particularly important in *children in whom the attack may begin with* diarrhea

Persistence or exacerbation of symptoms in spite of the preceding therapy, usually means obstruction or abscess formation somewhere in the upper urinary tract If this is located, temporary bypassing or other means of drainage may be required This is a specific urologic problem, and decision as to exact treatment should be arrived at through consultation Definitive surgery, such as nephrostomy, removal of stones, prostatectomy or nephrectomy, is post*poned until the acute infection has been* brought under control, if that is possible *However good surgical principles must be* followed in providing the necessary drainage *for renal or perinephritic collections of pus* When pyelonephritis complicates pregnancy, *ureteral catheter drainage may be necessary* for a period The antibiotics have changed the gravity of this combination and it is now hardly necessary to resort to termination of the pregnancy to relieve ureteral obstruction

## CHRONIC PYELONEPHRITIS

Chronic pyelonephritis is probably the most common chronic organic renal disease if one excludes hypertensive renal arteriolosclerosis It is often overlooked because of the insidious nature of its course in many cases and the long period it requires to produce renal insufficiency or other important signs A few cases first come to light because of a hypertensive syndrome associated with a predominant unilateral pyelonephritis of the atrophic variety In many cases uremia follows decades of smouldering or recurrent infection and gradual destruction and scarring of the kidneys For paraplegics and others with neurologic bladder disease chronic pyelonephritis still commonly shortens life

*Etiology and Pathogenesis* —The same pyogenic bacteria present in the urinary tract in acute pyelonephritis are *implicated* in the chronic process The repeated infec-

tion of renal parenchyma is favored by the underlying obstructive lesions and later the scars and deformities produced by the inflammation itself Gradually as more and more tubules are destroyed replacement fibrosis occurs this in turn strangles the preserved colloid filled tubules The glomeruli tend to hold out longer but ultimately succumb to the fibrosis around them In addition obliterative endarteritis adds to parenchymal ischemia and atrophy and may be associated with severe hypertension This entire process may be uniformly distributed throughout both kidneys and lead to smooth shrinkage or it may be focally expressed in chronic infiltrates and scars with intervening normal or hypertrophied parenchyma Often however asymmetrical inflammation and atrophy occurs in selected instances these may be responsible for a hypertensive syndrome including the malignant phase Secondary hypertensive vascular changes may occur in the larger, better-functioning kidney Pelvic and calyceal scarring with dilatation proximal to obstruction is responsible for pyelographic changes helpful in diagnosis

*Symptoms and Course* —Chronic pyelonephritis may run a variety of courses Some patients after a severe first attack continue to have periods of low grade fever general malaise fatigue unilateral or bilateral lumbar pain gastrointestinal disturbance mild secondary anemia poor tolerance for exercise and other nondescript symptoms These may last for weeks or months clear up and recur often with some frequency or burning on urination The urine may be grossly turbid or muddy and malodorous Other patients go for months or years without subjective symptoms but occasionally experience a few days of fever and dysuria with or without pain over one or both kidneys The course may be completely asymptomatic for a long time except for some anemia and borderline rises in blood pressure Prolonged and severe or accelerated hypertension may develop In patients with kidney stones attacks of colic and hematuria may precede recurrence of active symptoms of pyelonephritis and occasionally precipitate a fulminating infection with severe loin pain chills high fever general toxemia and prostration Acute pyonephrosis or multiple miliary abscesses are found in this condition, which is very dangerous when both kidneys are affected In a small number of young subjects with unilateral atrophic pyelonephritis a clinical syndrome develops with severe hypertension including the retinopathy of the malignant phase of hypertension left ventricular hypertrophy and attacks of acute left ventricular failure severe tension headaches dizziness vomiting and even convulsive encephalopathy Urinary tract infection may not be evident or suspected in this group until complete urographic and functional studies of each kidney are carried out In chronic pyelonephritis the symptoms of an underlying obstructive lesion may confuse or dominate the picture

In most patients with chronic pyelonephritis there is some degree of tubular impairment manifested by inability to concentrate the urine maximally The urea nitrogen level of the blood may be little elevated in the earlier stages Some hypochromic anemia is usually seen Edema never occurs except as a sign of heart failure in the hypertensive patient or in the very late stages of the disease when uremia is already at hand During the gradual development of renal insufficiency considerable acidosis may supervene without affecting the patient remarkably apart from dyspnea on exertion Occasionally the tubular impairment leads to a salt losing disturbance which may mimic the dehydration and salt depletion of Addison s disease In patients with calculous pyelonephritis secondary to hyperparathyroidism the blood chemical and bony changes of the primary disease will be detectable the former modified by renal insufficiency and its phosphate retention

*Diagnosis* —When the patient is first seen during an acute recurrence of chronic pyelonephritis it may be difficult without an adequate history to distinguish it from an initial acute attack Impaired renal function persisting after the acute symptoms have subsided speaks for the chronic renal involvement Roentgen findings of irregularities distortion dilatation or constriction of renal pelves or calyces often asym

cultures of the urine are very helpful in some cases. Also, in acute glomerulonephritis which is usually produced by the beta-hemolytic streptococcus, the antistreptolysin titer in the serum will be high. Acute cystitis is usually distinguished from pyelonephritis by the frequency of urination, pain at beginning and end of urination, milder general symptoms and terminal hematuria. Ordinarily, there is suprapubic or rectal tenderness but no lumbar tenderness. Urinary casts are absent, and the proteinuria is more in proportion to the hematuria and pyuria. "Pyelitis" is not to be differentiated from what it really is—pyelonephritis.

*Treatment.*—The treatment of acute pyelonephritis begins with relief of any urinary-tract obstruction. In children, the possibility of congenital strictures, valves, aberrant renal vessels, malposition, reduplication and other anomalies must be considered once the acute infection has been brought under control.

*Specific antibiotic treatment* will vary with the results of urine cultures. While awaiting their outcome, a combination of penicillin and sulfa or streptomycin or aureomycin, in full dosage is given for the first few days. The sensitivity of urinary bacteria should be tested if there is any question about the clinical response. Aureomycin or chloramphenicol may have to be used for relatively resistant gram-negative bacilli. To promote a high concentration of antibiotic in the urine, the fluid intake should not be forced too high early in the course unless there is considerable dehydration. Treatment with antibiotics should be continued until pyuria has ceased and repeated urine cultures at intervals of several days or a week show no growth of the offending bacteria.

*Symptomatic therapy* includes maintenance of adequate hydration, prescription of a light diet (or parenteral feeding if necessary), the use of analgesics and sedation as indicated, the administration of supportive blood transfusions for anemia, and good nursing during the recurrent chills, fever and sweats. The bowels should be kept open with mild laxatives or small enemas. Tympanites or ileus may require small doses of prostigmine. Excessive vomiting may be stopped by gastric intubation and aspiration. Careful replacement of fluids lost is necessary to prevent dehydration and electrolyte imbalance. This is particularly important in children in whom the attack may begin with diarrhea.

Persistence or exacerbation of symptoms in spite of the preceding therapy, usually means obstruction or abscess formation somewhere in the upper urinary tract. If this is located, temporary by passing or other means of drainage may be required. This is a specific urologic problem, and decision as to exact treatment should be arrived at through consultation. Definitive surgery, such as nephrostomy, removal of stones, prostatectomy or nephrectomy, is postponed until the acute infection has been brought under control, if that is possible. However, good surgical principles must be followed in providing the necessary drainage for renal or perinephritic collections of pus. When pyelonephritis complicates pregnancy, ureteral catheter drainage may be necessary for a period. The antibiotics have changed the gravity of this combination, and it is now hardly necessary to resort to termination of the pregnancy to relieve ureteral obstruction.

## CHRONIC PYELONEPHRITIS

Chronic pyelonephritis is probably the most common chronic organic renal disease if one excludes hypertensive renal arteriolosclerosis. It is often overlooked because of the insidious nature of its course in many cases and the long period it requires to produce renal insufficiency or other important signs. A few cases first come to light because of a hypertensive syndrome associated with a predominant unilateral pyelonephritis of the atrophic variety. In many cases uremia follows decades of smouldering or recurrent infection and gradual destruction and scarring of the kidneys. For paraplegics and others with neurologic bladder disease chronic pyelonephritis still commonly shortens life.

*Etiology and Pathogenesis.*—The same pyogenic bacteria present in the urinary tract in acute pyelonephritis are implicated in the chronic process. The repeated infec

with the fluid intake increased to produce a larger urine volume There is no reason for restriction of salt Any febrile episode should be looked upon with suspicion as a possible index of recurrent renal infection Urine culture and examination of the urinary sediment and culture are indicated at such period

## TUBERCULOUS PYELONEPHRITIS

Tuberculous pyelonephritis is a prevalent and dangerous sequel to pulmonary tuberculosis or other source of hematogenous renal infection Because of its progressive and destructive course its ultimate extension to the urinary tract and the secondary involvement of the seminal vesicles the epididymis and the prostate as well as the risk of retrograde infection to the second kidney tuberculosis of the kidney must be diagnosed as early as possible It should be considered whenever a patient with any urinary tract symptoms and pyuria fails to respond to the usual treatment

*Etiology and Pathogenesis* —Tuberculous infection of the kidney begins with the formation of a tubercle around the bacilli in a terminal vessel of either the cortex or the medullary pyramid Caseation surrounding granulomatous inflammation and destruction of parenchyma proceed until the infection breaks through into the collecting ducts or ulcerates into one of the calyces of the renal pelvis Hemorrhage secondary infection cicatricial fibrosis and calcification occur in time Hydronephrosis and pyonephrosis may develop from ureteropelvic obstruction Rarely the ureter may be stenosed and the entire kidney closed off and rendered functionless though no longer a source of descending infection Tuberculous pyelonephritis may lead to an atrophic scarred and calcified kidney with considerable endarteritis This endarteritis may form a background for severe renal hypertension but it is amenable to nephrectomy in young patients The ulcerative changes in one or more calyces and the associated spasm or scarring furnish the basis for the diagnostic pyelographic findings In later stages the tuberculous cystitis at the ureteral orifice yields visual evidence during cystoscopy

*Symptoms and Course* —There may be no urinary-tract symptoms at the onset only the general manifestations of mild infection — malaise fatiguability slight fever night sweats weight loss and vague aches and pains More typically there are frequent and somewhat painful urination with bloody or cloudy urine variable renal or ureteral colic and at times attacks of acute pyelonephritis owing to mixed infection The suspicion of renal tuberculosis is sometimes aroused only by symptoms and signs of chronic epididymitis or prostatitis It is characteristic of uncomplicated renal tuberculosis that the urine is likely to be acid during pyuria and is sterile for ordinary pyogenic bacteria Albuminuria and turia are variable and not associated with casts Cultures of the concentrated sediment from 24-hour urines or samples obtained during urologic examination will often reveal acid fast bacilli Guinea-pig inoculation is necessary for absolute diagnosis Renal function and blood pressure are normal in the ordinary patient Renal insufficiency means extensive bilateral involvement *In nearly all* patients there will be definite *x* ray or other evidence of pulmonary tuberculosis or some other less common source of hematogenous renal infection

*In most patients with tuberculous pyelonephritis the course* is relentlessly progressive unless interrupted by treatment Apart from successive involvement of the lower urinary and genital tracts the possibility of secondary miliary spread via the circulation always threatens Suppurating fistulous tracts from infected urogenital structures add to the misery of the patient already plagued by severe bladder symptoms Amyloidosis may develop in these patients

*Diagnosis* —Evidence of previous pulmonary or bone tuberculosis or *x* ray or sputum findings of present infection are exceedingly important diagnostic aids Fine calcification focally in the renal *x* ray shadow is very suggestive of tuberculous pyelonephritis Careful and expert urologic studies urine cultures and guinea pig inoculation

metrical in the two kidneys, point to a chronic process. The presence of urolithiasis, ureteral stricture, prostatic hypertrophy, or urethral obstruction furnishes a diagnostic background for chronic urinary tract infection. The differential diagnosis from chronic glomerulonephritis is ordinarily easy. In the late pre-uremic stages of either disease the urine may not be helpful nor will any of the clinical findings be specific. If the history of the onset and course is not clearly available only retrograde pyelography may furnish the diagnostic clues to pyelonephritis. In patients over 50 chronic glomerulonephritis is less common than is pyelonephritis. Any demonstration of a significant urinary tract obstruction or anomaly of development should throw the balance heavily in favor of pyelonephritis. The differentiation from essential hypertension and hypertensive renal vascular disease usually offers no problem in cases with an adequate history. However difficulties in diagnosis may arise in the stage of severe renal insufficiency, when the blood pressure tends to rise, sometimes rapidly. Here a demonstration of the signs of prolonged hypertension—in the cardiac, cerebral, and retinal changes—should be possible in non-pyelonephritic cases. Small kidneys even without deformities of the pelves or calyces, suggest chronic pyelonephritis rather than hypertensive renal vascular disease. A family history of hypertensive disease may confuse the situation in a chronic pyelonephritic. Some clinicians believe that the hypertensive background is more important than the chronic renal infection in producing hypertension in these patients. The differential diagnosis of the malignant hypertension associated with unilateral atrophic pyelonephritis in children and young adults is exceedingly important. Some of these patients can be cured by nephrectomy. Hence every person with considerable hypertension who does not have a typical glomerulonephritis should undergo intravenous and if necessary retrograde pyelography. The question of the predominantly unilateral involvement by pyelonephritis or renal-vascular changes can only be settled by meticulous renal function studies of each kidney. Chronic pyelonephritis in pregnancy is usually distinguished from the hypertensive toxemias by the greater evidence of infection and the lesser effect on the blood pressure. Furthermore, edema is not part of the picture of pyelonephritis. Diabetic glomerulosclerosis may be confused with chronic pyelonephritis as a cause of renal disease in diabetics. Here the clinical presence of noncardiac edema and of doubly refractile lipoid cells and casts in the urine of patients with glomerulosclerosis is of great diagnostic value. The two conditions may be combined in diabetics toward the end of life.

*Prognosis.*—In the average adult case chronic pyelonephritis lasts for a few decades and then winds up in uremia or some hypertensive complication. The hazards of necessary surgical procedures also affect the prognosis, but the antibiotics have improved the outlook remarkably.

*Treatment.*—The best treatment for chronic pyelonephritis is *preventive*. This applies to the recognition and relief of urinary tract obstruction whenever feasible. The chemotherapy and antibiotic treatment of urinary infection is most important but can be carried out intelligently only after frequent urine cultures and sensitivity studies. Unfortunately the gram negative bacilli especially of the Aerobacter, Proteus and Pseudomonas group are likely to develop resistance to most of the sulfa drugs and antibiotics sooner or later. They should therefore be treated with full doses and for specific periods with interruption after several negative urine cultures. As long as calculi, large prostates, strictures or other obstructive lesions persist reinfection is inevitable. To this extent chronic pyelonephritis is a surgical disease and good urological surgery will act as a prophylactic. Foci of infection such as ulcerative colitis, decubital ulcers and other portals of entry of bacteria dangerous to the kidneys should be properly managed. General supportive measures, correction of anemia, bed rest during active renal infection and modification of diet as necessitated by severe renal insufficiency or hypertensive heart failure make up the *symptomatic therapy*. In the average case of chronic pyelonephritis the diet should be normal

with the fluid intake increased to produce a larger urine volume There is no reason for restriction of salt Any febrile episode should be looked upon with suspicion as a possible index of recurrent renal infection Urine culture and examination of the urinary sediment and culture are indicated at such periods

## TUBERCULOUS PYELONEPHRITIS

Tuberculous pyelonephritis is a prevalent and dangerous sequel to pulmonary tuberculosis or other source of hematogenous renal infection Because of its progressive and destructive course its ultimate extension to the urinary tract and the secondary involvement of the seminal vesicles the epididymis and the prostate as well as the risk of retrograde infection to the second kidney tuberculosis of the kidney must be diagnosed as early as possible It should be considered whenever a patient with any urinary tract symptoms and pyuria fails to respond to the usual treatment

*Etiology and Pathogenesis* —Tuberculous infection of the kidney begins with the formation of a tubercle around the bacilli in a terminal vessel of either the cortex or the medullary pyramid Caseation surrounding granulomatous inflammation and destruction of parenchyma proceed until the infection breaks through into the collecting ducts or ulcerates into one of the calyces of the renal pelvis Hemorrhage secondary infection cicatricial fibrosis and calcification occur in time Hydronephrosis and pyonephrosis may develop from ureteropelvic obstruction Rarely the ureter may be stenosed and the entire kidney closed off and rendered functionless though no longer a source of descending infection Tuberculous pyelonephriti may lead to an atrophic scarred and calcified kidney with considerable endarteritis This endarteritis may form a background for severe renal hypertension but it is amenable to nephrectomy in young patients The ulcerative changes in one or more calyces and the associated spasm or scarring furnish the basis for the diagnostic pyelographic findings In later stages the tuberculous cystitis at the ureteral orifice yields visual evidence during cystoscopy

*Symptoms and Course* —There may be no urinary tract symptoms at the onset only the general manifestations of mild infection — malaise fatiguability slight fever night sweats weight loss and vague aches and pains More typically there are frequent and somewhat painful urination with bloody or cloudy urine variable renal or ureteral colic and at times attacks of acute pyelonephritis owing to mixed infection The suspicion of renal tuberculosis is sometimes aroused only by symptoms and signs of chronic epididymitis or prostatitis It is characteristic of uncomplicated renal tuberculosis that the urine is likely to be acid during pyuria and is sterile for ordinary pyogenic bacteria Albuminuria and turia are variable and not associated with casts Cultures of the concentrated sediment from 24 hour urines or samples obtained during urologic examination will often reveal acid fast bacilli Guinea pig inoculation is necessary for absolute diagnosis Renal function and blood pressure are normal in the ordinary patient Renal insufficiency means extensive bilateral involvement In nearly all patients there will be definite *x* ray or other evidence of pulmonary tuberculosis or some other less common source of hematogenous renal infection

In most patients with tuberculous pyelonephritis the *course* is relentlessly progressive unless interrupted by treatment Apart from successive involvement of the lower urinary and genital tracts the possibility of secondary miliary spread via the circulation always threatens Suppurating fistulous tracts from infected urogenital structures add to the misery of the patient already plagued by severe bladder symptoms Amyloidosis may develop in these patients

*Diagnosis* —Evidence of previous pulmonary or bone tuberculosis or *x* ray or sputum findings of present infection are exceedingly important diagnostic aids Fine calcification focally in the renal *x* ray shadow is very suggestive of tuberculous pyelonephritis Careful and expert urologic studies urine cultures and guinea pig inoculation

are indispensable for the diagnosis. The differential diagnosis includes urolithiasis, tumors, ordinary pyogenic pyelonephritis, nonspecific chronic cystitis or ureteritis, and atypical glomerulonephritis or glomerulitis. In rare cases, the diagnosis cannot be established until histologic studies are made of the removed kidney.

*Prognosis.*—The prognosis depends on early diagnosis, the individual's resistance, the maintenance of good nutrition and morale, adequate rest and time for healing and the control of spread of infection. The last can now be accomplished partly with the aid of streptomycin and other chemotherapy, but surgical removal of the grossly infected organ is usually still necessary. The antibiotics are of great value in clearing up residual sinuses and infected ureteral stumps.

*Treatment.*—Conservative early treatment of tuberculous pyelonephritis includes the proper use of streptomycin and often leads to the arresting or even healing of the smaller renal lesions associated with tubercle bacilluria.

In renal tuberculosis nephrectomy is indicated when there are diagnostic pyelographic changes and large ulcerating lesions. The pre- and postoperative periods should include streptomycin and p-amino-salicylic acid therapy. If the remaining kidney and lower urogenital tract are uninvolved, the patient may be considered cured but nevertheless should be trained to lead the life of an arrested case of tuberculosis. For complete security, urine cultures should be made frequently, even in the absence of symptoms.

## VASCULAR RENAL DISEASES

Vascular renal diseases include ordinary *hypertensive renal arterio and arteriolosclerosis*, diabetic glomerulosclerosis and the occlusive, inflammatory and allergic diseases of the kidneys.

## RENAL ARTERIAL OCCLUSION

Major renal arterial occlusion by arteriosclerotic thrombosis, embolism or inflammatory disease may be recognized when it occurs suddenly, by the development of renal pain, hematuria, hypertension at times, and evidence of loss of renal function on the affected side. In bilateral involvement, oliguria or anuria and uremia, usually with hypertensive features, appear quickly. Occlusion of small arterial branches with resulting small infarcts, may be easily overlooked unless the transitory gross or microscopic hematuria is detected. In the gradual involvement of one renal artery there may be no signs or symptoms of note if the other kidney is normal. Even accurate clearance tests will be difficult to interpret unless one thinks of the possibility of unilateral loss of renal function. Hypertension may result from unilateral renal arterial occlusion, pyelographic studies will detect unilateral failure of renal function. The presence of subacute bacterial endocarditis, acute myocardial infarction, auricular fibrillation, or other source of arterial embolism suggest major renal infarction. In case of septic emboli, renal suppuration will occur and produce the general symptoms of severe pyelonephritis.

*Treatment.*—Treatment is conservative and symptomatic. Nephrectomy is necessary for gross necrosis and suppuration and in the rare cases of Goldblatt hypertension diagnosed during life. In bilateral involvement, treatment is usually of no avail because of the irreversible uremia.

## RENAL VENOUS THROMBOSIS

Renal venous thrombosis may occur by extension from inflammation within the kidney, neoplastic invasion (as in hypernephromas) or extension of thrombosis from the inferior vena cava or as the result of the tendency to blood coagulation in certain diseases and cachectic states. There may be no obvious symptoms and only mild lumbar pain and only microscopic hematuria. On the other hand, renal venous thrombosis may begin with severe lumbar pain and tenderness, enlargement of the kidney and frank hematuria. When the disease is unilateral and gradual in occurrence a remarkable syndrome may result characterized by massive proteinuria, nephrotic edema and ascites, low serum albumin and hypercho-

lesterolemia even doubly refractile lipoid cells and casts may be found in the urine Renal function is usually impaired but not so seriously as one might expect Sudden bilateral occlusion of the renal veins usually causes death from uremia, often with hyper tensive symptoms

*Treatment* —Treatment is symptomatic to tide the patient over the period necessary for the development of collateral circulation Edema is managed as in chronic glomerulo nephritis and renal insufficiency in the usual manner

## ALLERGIC RENAL VASCULAR DISEASE

Allergic renal vascular disease includes the syndrome of periarteritis nodosa or polyarteritis the visceral lupus syndrome the visceral rheumatic purpuras and other affections of the arteries in infectious dis eases Unless hypertension edema urinary sediment changes and renal impairment are observed during the course of these diseases the renal vascular involvement will not be suspected Treatment is for the underlying condition and renal impairment if significant (For further discussion *see* section on Glomerulitis)

## ACUTE NECROTIZING TUBULAR NEPHROSES

Acute necrotizing tubular nephroses re sult from heavy metal and other inorganic and organic poisons of which mercury bis muth tartrates and carbon tetrachloride are representative from the hypoxic or ischemic necrosis following prolonged states of shock whether of hemorrhagic traumatic or infectious toxic origin from the degener ation and calcification due to endocrine and metabolic disturbances like hyperparathyroidism hypervitaminosis D or severe alkalosis from the tubular changes associated with acute hemolytic crises and from the intrarenal obstructive nephropathy ac companying precipitation of Bence Jones protein sulfa uric acid and other substances of poor solubility in the urine under certain conditions In general the tubular neph roses are acute and short lived due to rapid regeneration of tubular epithelium Once damage is severe enough to produce symptoms fatal oliguria and uremia are likely to ensue unless the patient can be tided over the few weeks required for restoration of anatomical tubular integrity

*Etiology and Pathogenesis* —The nephroses due to mercury bismuth uranium arsenic and other metallic poisons presumably result from direct precipitation or irreversible inactivation of important enzyme proteins in the tubular epithelium enzyme proteins that control the normal selective transfer mechanisms Glomerular filtration may still go on if the circulation is in good shape, but the filtrate entirely diffuses back through the damaged and necrotic proximal tubules Different chemical poisons may act maximally on the different segments of the proximal convoluted tubule but the net clinical result is essentially the same Even in the so-called lower nephron nephrosis associated with a large variety of conditions producing circulatory shock and renal hypoxia, the upper part of the nephron is probably not anatomically intact, nor is there good evidence that the severe renal dysfunction is chiefly of distal nephron origin In the nephroses characterized by the precipitation of blood pigment sulfa crystals Bence-Jones protein and other insoluble material in the lumen of the tubules, it is still uncertain how much this intrarenal obstruction interferes with kidney function The associated hemodynamic alterations and the interstitial inflammatory often granulomatous reaction in the kidney may be far more important in the clinical effect The nephroses occurring during severe alkalosis of pyloric or high intestinal obstruction or following excessive aspiration of gastric contents often cause much calcium deposition in necrotic or atrophic tubules Similarly acute exacerbations of hyperparathyroidism may lead to marked calcium infiltration of tubules and arterioles The nephroses produced by diethylene glycol or hypertonic sucrose cause striking hydropic swelling of proximal tubular epithelium, swelling sufficient to cause destruction of the lumen and probably cessation of filtration by increasing intracapsular pressure The attractive thesis that increased intrarenal

are indispensable for the diagnosis The differential diagnosis includes urolithiasis tumors ordinary pyogenic pyelonephritis, nonspecific chronic cystitis or ureteritis, and atypical glomerulonephritis or glomerulitis In rare cases, the diagnosis cannot be established until histologic studies are made of the removed kidney

*Prognosis* —The prognosis depends on early diagnosis, the individual's resistance the maintenance of good nutrition and morale adequate rest and time for healing and the control of spread of infection The last can now be accomplished partly with the aid of streptomycin and other chemotherapy but surgical removal of the grossly *infected organ is usually still necessary* The antibiotics are of great value in clearing up residual sinuses and infected ureteral stumps

*Treatment* —Conservative early treatment of tuberculous pyelonephritis includes the proper use of streptomycin and often leads to the arresting or even healing of the smaller renal lesions associated with tubercle bacilluria

In renal tuberculosis nephrectomy is indicated when there are diagnostic pyelographic changes and large ulcerating lesions The pre- and postoperative periods should include streptomycin and p-amino salicylic acid therapy If the remaining kidney and lower urogenital tract are uninvolved the *patient may be considered cured but nevertheless* should be trained to lead the life of an arrested case of tuberculosis For complete security urine cultures should be made frequently even in the absence of symptoms

## VASCULAR RENAL DISEASES

Vascular renal diseases include ordinary *hypertensive renal arterio and arteriolosclerosis* diabetic glomerulosclerosis and the occlusive inflammatory and allergic diseases of the kidneys

## RENAL ARTERIAL OCCLUSION

Major renal arterial occlusion by arteriosclerotic thrombosis embolism or inflammatory disease may be recognized when it occurs suddenly, by the development of renal pain, hematuria hypertension at times, and evidence of loss of renal function on the affected side In bilateral involvement, oliguria or anuria and uremia, usually with hypertensive features appear quickly Occlusion of small arterial branches with resulting small infarcts, may be easily overlooked unless the transitory gross or microscopic hematuria is detected In the gradual involvement of one renal artery, there may be no signs or symptoms of note if the other kidney is normal Even accurate clearance tests will be difficult to interpret unless one thinks of the possibility of unilateral loss of renal function Hypertension may result *from unilateral renal arterial occlusion* pyelographic studies will detect unilateral failure of renal function The presence of subacute bacterial endocarditis acute myocardial infarction, auricular fibrillation, or other source of arterial embolism suggest major renal infarction In case of septic emboli renal suppuration will occur and produce the general symptoms of severe pyelonephritis

*Treatment* —Treatment is conservative and symptomatic Nephrectomy is necessary for gross necrosis and suppuration and in the rare cases of Goldblatt hypertension diagnosed during life In bilateral involvement treatment is usually of no avail because of the irreversible uremia

## RENAL VENOUS THROMBOSIS

Renal venous thrombosis may occur by extension from inflammation within the kidney neoplastic invasion (as in hypernephromas) or extension of thrombosis from the inferior vena cava or as the result of the tendency to blood coagulation in certain diseases and cachectic states *There may be no* obvious symptoms and only mild lumbar pain *and only microscopic hematuria* On the other hand renal venous thrombosis may begin with severe lumbar pain and tenderness enlargement of the kidney, and frank hematuria When the disease is unilateral and gradual in occurrence a remarkable syndrome may result characterized by massive *proteinuria nephrotic edema and* ascites low serum albumin, and hypercho-

precipitation in the urinary tract must be remembered If urine cannot be obtained and blood has not been drawn early enough the exact diagnosis may be difficult although the gravity of the renal disturbance will be obvious An *x* ray of the abdomen to exclude urolithiasis is often helpful Special tests are necessary to determine the etiology of paroxysmal hemoglobinurias and clinical hemolytic diseases

*Prognosis* —The prognosis varies with the degree of hemolysis the severity of the initial circulatory reaction the distribution of erythrocytic thrombi and emboli the nature of the underlying hemolytic disease or the gravity of the condition for which blood transfusion was given and the type of treatment given early and later A hemolytic nephrosis is always potentially fatal when severe oliguria or anuria is present However as long as even 50 or 100 cc of urine are excreted daily the outlook is not hopeless If the patient can be tided over the first 10 days and given time for tubular regeneration the prognosis improves rapidly Nearly all the deaths occur within the first two weeks

*Treatment* —Prevention is of paramount importance here at least with regard to incompatible blood transfusions Careful inquiry into previous transfusion experiences meticulous typing and subtyping of blood Rh typing and cross matching with free use of the Coombs test are worth the effort they require During blood transfusions close medical observation is imperative As a routine a sample of venous blood should be drawn at the end of each transfusion even when there is no reaction and immediately upon any suggestive symptoms Urine should be obtained before during and after each transfusion and carefully examined The urinary output of the patient should be recorded for at least 24 hours giving the volume and appearance of each specimen Blood transfusion of patients with hemolytic crises and severe anemia due to congenital defects or acquired hemolysins should be undertaken only after careful review of previous response to such treatment When the etiology of an attack of hemoglobinuria is known every effort should be made to prevent recurrent paroxysms by appropriate treatment of the etiological disease malaria or syphilis or the careful avoidance of exposure to cold strenuous muscular exercise (march hemoglobinuria) or the ingestion of the favus bean by susceptible persons

*Symptomatic treatment* of hemolytic nephrosis consists of the emergency management of the immediate circulatory shock with irradiated plasma or serum albumin and the later management of anuria and uremia Retyped and rematched blood may have to be given early or later for acutely dangerous anemia The use of hypertonic sodium bicarbonate or lactate solution intravenously as soon as the hemolysis is suspected may help prevent further precipitation of hemoglobin or its derivatives in the renal tubular lumen provided urine formation is still active Once urine flow is suppressed the administration of sodium salts simply aggravates the tendency to pulmonary and other edema and may cause dangerous alkalosis When diuresis returns specific electrolyte administration sufficient to offset urinary and extrarenal loss is necessary to prevent dangerous depletion and acidosis No diuretic drug is of value during hemolytic nephrosis and much harm may result from the use of such a drug However aminophyllin may be given for acute bronchospasm

## TRAUMATIC OR MYOGLOBIN NEPHROSIS

*Traumatic nephrosis* or crush syndrome accompanies crushing skeletal injuries involving muscle damage and circulatory shock It is a common result of the bombing of cities mining and other industrial accidents and automobile injuries It differs from other forms of acute ischemic nephrosis associated with prolonged shock in that myoglobin released from damaged muscle may precipitate as pigment casts in the lumen of renal tubules or appear in the urine like hemoglobin in hemolytic nephroses The exact toxic role of this pigment is still debatable

*Symptoms and Course* —The onset of oliguria and anuria following a crushing injury is often overlooked in the emergency

pressure due to edema is responsible for the anuria and uremia in most of the acute tubular nephropathies is not supported by sufficient physiological or therapeutic evidence. In practically all the nephroses in which the injurious factor acts only at one time or on a few occasions, the patient recovers from the original renal impairment or the general effects of the agent. Continuous or frequently repeated renal damage as a result of multiple myeloma, hyperparathyroidism or prolonged hypercalcemia of other origin causes foci of tubular atrophy, vascular damage, and interstitial fibrosis. These eventually combine to produce chronic irreversible renal disease.

## HEMOLYTIC NEPHROSIS

*Hemolytic, hemoglobinuric or blood-pigment nephrosis* is an important type of renal disease in these days of widespread use of blood transfusions. Apart from its etiology and certain special clinical features, its course and prognosis are quite similar to mercurial nephrosis (Chapter 13). It is included ordinarily among the so called lower nephron nephroses, but the upper nephron is probably severely affected functionally, if not anatomically.

*Etiology and Pathogenesis.*—Any acute hemolytic reaction, whether from incompatible blood transfusion, or any other cause may give rise to blood pigment nephrosis. The pathogenesis of the renal injury is now known to be much more complicated than was postulated by the original theory of simple obstruction of renal tubules by pigment casts. Pathological and experimental observations have led to the conclusion that the obstruction by pigment casts is relatively unimportant. Hemodynamic changes and renal hypoxia or anoxia are far more constant and significant findings. Direct toxic action of hemolyzed blood or of reabsorbed ferric iron on tubular epithelium may occur, too. Auxiliary factors like dehydration and strongly acid urine also play a role. The earliest change is marked renal ischemia and reduced glomerular filtration, soon followed by depression of tubular function. Secondary vascular thromboses and interstitial inflammation in the kidneys add to the functional disorganization. The general effects of circulatory collapse and the specific local effects of the etiological condition complicate the pathogenesis of the hemolytic nephroses.

*Symptoms and Course.*—The clinical picture varies with the underlying disturbance, but the renal syndrome is relatively uniform. The patient often first complains of lumbar pain or abdominal distress and may pass blood or reddish brown urine. Within a few hours, the urine output may fall to a very low level or cease entirely. Oppression in the chest, dyspnea, headache, vomiting, chill and fever, pains in the limbs and circulatory shock may occur in the more severe cases. There may be no obvious symptoms after a blood transfusion until anuria ensues. Slight to moderate icterus of the scleræ may be seen the day after the hemolytic episode but is often overlooked. The liver and spleen may become palpable and slight general edema may develop, especially if the patient continues to take food and fluids. The blood pressure may fall to shock levels in the initial reaction, if severe, but returns to the control value and later rises above normal as anuria continues. Severe anemia usually appears. Leukocytosis may be marked. The progression of asthenic uremia begins after a few days and takes its usual course to coma and death in from one to three weeks, unless urine flow is reestablished. Cerebral, cardiac or pulmonary manifestations from the original hemolytic disturbance will complicate the clinical picture.

*Diagnosis.*—The demonstration of hemoglobinuria with little or no hematuria and the finding of blood pigment casts is pathognomonic. If at the same time a blood sample is drawn very carefully to avoid hemolysis and free hemoglobin is seen in the serum, absolute confirmation is obtained. Since free hemoglobin is rapidly removed from the blood, the sample must be obtained immediately upon the suspicion of hemolysis. A few hours later the serum bilirubin will usually be elevated temporarily. The scleræ and skin later become icteric. Differentially, one must consider other red pigments in the urine, such as porphyrins, and hematuria of renal or lower urinary-tract origin. Sulfa

ureters usually lead to rapid improvement. Sulfa nephrosis results from direct toxicity of or allergic reaction to the drug and is not related to blood levels or urinary concentration. The kidneys may or may not show sulfa crystals in the tubular lumen or epithelium. They do show degeneration and necrosis of the nephrons, especially the distal nephrons, with considerable interstitial inflammation, arteritis and arteriolitis often granulomatous and edema. The glomeruli are also involved in the more severe cases. Lesions in other organs including the heart and the brain are not uncommon but may be difficult to diagnose clinically. The renal functional disorganization is the same as in other toxic nephroses; however, the kidneys may excrete urine in considerable amounts after infusion of isotonic saline, but with practically no sodium or chloride. The result is a remarkable elevation of the serum levels to as high as 180 meq. per liter for sodium and 150 meq. for chloride. This is usually associated with severe encephalitic symptoms and, unless early recognized and treated with nonsaline fluids, very likely to end fatally (Luetscher *et al.*).

## ALKALOTIC NEPHROSIS

Alkalotic nephrosis represents the late stages of severe renal damage produced by alkalosis, dehydration, cation deficits and other metabolic disturbances resulting from loss of upper gastrointestinal secretions, chiefly the gastric juice, by vomiting or tubal aspiration. This alkalosis in the past was often aggravated by administration of soluble alkali salts as antacids and the use of rigid Sippy diets in the milk and cream stage with their low sodium-chloride content. Refusal of food and fluids by the anorexic patient led to rapid azotemia in many instances. Nowadays, postoperative gastric suction to relieve distention and vomiting is a major cause of severe alkalosis.

*Etiology and Pathogenesis.*—When the gastric contents are lost for one reason or another, chloride leaves the body without its serum partner sodium. Bicarbonate, always available, expands to take the place of the lost chloride in extracellular fluids. This results in increased pH or alkalosis but is partly compensated for by higher excretion of sodium bicarbonate in an alkaline urine. However, as loss of upper gastrointestinal contents continues, not only hydrochloric acid but sodium chloride and water are lost and not replaced because of anorexia and poor intake or absence of salt in the dextrose solutions infused. Ultimately the serum sodium falls to levels of 120 milliequivalents or less in spite of increasing bicarbonate and decreasing chloride. At this point, dehydration and hemoconcentration have usually caused hemodynamic changes with deleterious effects on renal blood flow, glomerular filtration and tubular function. The kidney stops excreting sodium entirely, whether as bicarbonate or chloride, and one observes the paradox of an acid urine in the presence of severe internal alkalosis. Tubular degeneration, calcification and focal necrosis make their appearance and convert a functional into an organic renal disease with complete functional disorganization and rapid development of azotemia aggravated by toxic catabolism of protein. The process is reversible if recognized in time and runs the course of any other severe nephrosis except for the initial alkalosis. The alkalosis is gradually neutralized by uremic acidosis, the absence of anuria and the frequent depletion of potassium.

*Symptoms and Course.*—The alkalotic and renal symptoms often develop insidiously or are lost in the manifestations of heavy sedation, postoperative distress and cardiovascular and cerebral symptoms in the post hemorrhagic or postoperative states, especially in older age groups. Anorexia, nausea and vomiting, weakness, nervous irritability or apathy, confusional or delirious reactions, drowsiness or restless insomnia, stupor and twitchings (occasionally tetanic convulsions), respiratory difficulty and muscular paralysis (due to severe hypopotassemia)—any or all of these may occur. The patient usually shows considerable weight loss and signs of tissue dehydration. Muscular hyperesthesia is common. Hypotension and tachycardia are frequent. The urine output is often reduced to oliguric levels but there is seldom anuria. The urine is at first alka

of releasing the victim from the cause of the accident and in treating his shock. Characteristically, tremendous swelling of the injured limbs occurs after the crushing object or debris is removed. In the next few days, urinary output is insignificant and the clinical and chemical sings of asthenic uremia develop. The blood pressure may remain at low levels even after blood transfusion, and anemia replaces early hemoconcentration. The originally dark-reddish or chocolate-brown urine becomes lighter and its specific gravity isosthenuric in spite of the very small volume. Proteinuria, pigment and other casts, variable microscopic hematuria, and epithelial cells are found in the first urine the patient passes after the injury. Death occurs from uremia in most cases within a week or two even if the patient survives his original injuries. In the more fortunate group, urine flow is resumed gradually and after a diuretic phase with poor renal function, complete restitution occurs.

*Diagnosis.*—Diagnosis is easy whenever the urine is examined shortly after the crushing injury and before much blood has been transfused. After the treatment of shock the anuria may be confused with one arising from hemolysis. Spectroscopic analysis of the urinary pigment is required to differentiate myoglobin from hemoglobin derivatives.

*Treatment.*—Treatment consists in the management of traumatic shock, blood and plasma transfusion, compression bandaging of affected limbs to prevent massive swelling and sequestration of circulating volume into the crushed areas, early use of hypertonic sodium bicarbonate solution intravenously to keep the urine alkaline and prevent precipitation of myoglobin or metmyoglobin and prescription of a diet without protein or electrolytes but high in carbohydrate and fat, the administration of intravenous hypertonic glucose when indicated with restriction of fluids to the very minimum necessary for fluid balance. Known electrolyte losses by vomitus or otherwise are compensated. In short, this is the standard treatment for anuric nephrosis while awaiting tubular regeneration. Artificial dialysis is indicated under proper conditions.

## CARBON TETRACHLORIDE NEPHROSIS

Carbon tetrachloride nephrosis is associated with liver damage and gastrointestinal disturbance that often obscure the renal injury. After the initial anorexia, vomiting, abdominal distress, and early jaundice, symptoms of nervous irritability, stupor or confusion develop. Then oliguria becomes apparent and blood-chemical analyses disclose the usual signs of severe renal insufficiency. The urine, originally highly concentrated and deeply colored, becomes increasingly dilute and contains protein and bile-stained casts, with few erythrocytes unless there is a general bleeding tendency from low prothrombin level. The blood pressure may rise moderately during the anuric phase and some general edema appear if the patient has received considerable parenteral fluids. The course is like that of any other acute toxic nephrosis but is complicated by the effects of hepatic insufficiency aggravated by acute alcoholism. However, since the poisoning ordinarily occurs by inhalation of fumes under industrial conditions of exposure rather than by ingestion as in the experimental animal, hepatic damage is not so severe and recovery may occur without gross residual symptoms or signs. The treatment is the same as for any other anuric nephrosis, but for the sake of the liver, lipotropic agents, choline and methionine, should be administered early. High protein feeding is out of the question, although it is sometimes instituted by error before the renal lesion is recognized.

## SULFA NEPHROSIS

Sulfa nephrosis is fortunately a vanishing disease, thanks to the introduction of antibiotic drugs and greater care in the use of sulfa drugs. In its pathogenesis it is to be distinguished from the mere precipitation of sulfa compounds in the urinary passages, in this case discontinuing use of the drug, forcing fluids and early irrigation of the bladder and

ureters usually lead to rapid improvement Sulfa nephrosis results from direct toxicity of or allergic reaction to the drug and is not related to blood levels or urinary concentration The kidneys may or may not show sulfa crystals in the tubular lumen or epithelium They do show degeneration and necrosis of the nephrons especially the distal nephrons with considerable interstitial inflammation, arteritis and arteriolitis often granulomatous and edema The glomeruli are also involved in the more severe cases Lesions in other organs including the heart and the brain are not uncommon but may be difficult to diagnose clinically The renal functional disorganization is the same as in other toxic nephroses however the kidneys may excrete urine in considerable amounts after infusion of isotonic saline but with practically no sodium or chloride The result is a remarkable elevation of the serum levels to as high as 180 meq per liter for sodium and 150 meq for chloride This is usually associated with severe encephalitic symptoms and unless early recognized and treated with nonsaline fluids very likely to end fatally (Luetscher *et al*)

## ALKALOTIC NEPHROSIS

Alkalotic nephrosis represents the late stages of severe renal damage produced by alkalosis dehydration cation deficits and other metabolic disturbances resulting from loss of upper gastrointestinal secretions *chiefly the gastric juice by vomiting or tubal* aspiration This alkalosis in the past was often aggravated by administration of soluble alkali salts as antacids and the use of rigid Sippy diets in the milk and cream stage with their low sodium-chloride content Refusal of food and fluids by the anorexic patient led to rapid azotemia in many instances Nowadays postoperative gastric suction to relieve distention and vomiting is a major cause of severe alkalosis

*Etiology and Pathogenesis* —When the gastric contents are lost for one reason or another chloride leaves the body without its serum partner sodium Bicarbonate always available expands to take the place of the lost chloride in extracellular fluids This results in increased pH or alkalosis but is partly compensated for by higher excretion of sodium bicarbonate in an alkaline urine However, as loss of upper gastrointestinal contents continues not only hydrochloric acid but sodium chloride and water are lost and not replaced because of anorexia and poor intake or absence of salt in the dextrose solutions infused Ultimately the serum sodium falls to levels of 120 milliequivalents or less in spite of increasing bicarbonate and decreasing chloride At this point dehydration and hemoconcentration have usually caused hemodynamic changes with deleterious effects on renal blood flow glomerular filtration and tubular function The kidney stops excreting sodium entirely whether as bicarbonate or chloride, and one observes the paradox of an acid urine in the presence of severe internal alkalosis Tubular degeneration calcification and focal necrosis make their appearance and convert a functional into an organic renal disease with complete functional disorganization and rapid development of azotemia aggravated by toxic catabolism of protein The process is reversible if recognized in time and runs the course of any other severe nephrosis except for the initial alkalosis The alkalosis is gradually neutralized by uremic acidosis the absence of anuria and the frequent depletion of potassium

*Symptoms and Course* —The alkalotic and renal symptoms often develop insidiously or are lost in the manifestations of heavy sedation postoperative distress and cardiovascular and cerebral symptoms in the post hemorrhagic or postoperative states especially in older age groups Anorexia nausea and vomiting weakness nervous irritability or apathy confusional or delirious reactions drowsiness or restless insomnia stupor and twitchings (occasionally tetanic convulsions) respiratory difficulty and muscular paralysis (due to severe hypopotassemia)—any or all of these may occur The patient usually shows considerable weight loss and signs of tissue dehydration Muscular hyperesthesia is common Hypotension and tachycardia are frequent The urine output is often reduced to oliguric levels but there is seldom anuria The urine is at first alka

line but is later dilute and neutral or acid, showing only a small amount of protein and little or no cellular sediment The blood chemistry shows rapidly rising non protein and urea nitrogen, and creatinine level The non protein nitrogen varies with the amount of glucose and fluid given and retained The striking feature is the serum electrolyte pattern—sodium levels low chloride values reduced to 80—50 per cent of normal, and $CO_2$ or bicarbonate values doubled A low serum potassium level is common As uremic acidosis due to retention of sulfates, phosphates and organic acids sets in the serum bicarbonate level falls toward normal Hemoconcentration, low-plasma volume, and elevated plasma-protein values are observed These, however are modified by blood loss and protein depletion or by dilution of infused fluids The outcome in neglected cases is death in uremia or sudden cardiac or respiratory arrest attributable in some cases to potassium deficiency Proper treatment of severe alkalosis however regularly brings about dramatic and rapid improvement Renal function may not become entirely normal for months or never in the older patients Repeated reccurrence of milder episodes of alkalosis in peptic ulcer patients on very prolonged high daily intake of milk and alkaline antacids including calcium carbonate, may lead to the remarkable syndrome of nephrocalcinosis This is characterized by renal insufficiency hypercalcemia without hypophosphatemia or hypercalciuria and calcium deposits in the scleral conjunctiva and cornea where it can be readily detected by slit lamp examination (Burnett *et al* ) The condition represents a chronic alkalotic and hypercalcemic nephrosis with severe organic damage gradually or episodically produced

*Diagnosis* —Ordinary prerenal azotemia and organic uremias of various origins are readily distinguished from alkalotic nephrosis by their clinical background and the absence of chemical alkalosis Adrenal-cortical insufficiency must be considered but the low serum-bicarbonate level and the high serum potassium level and the presence of significant sodium and chloride concentrations in the urine usually distinguish such insufficiency from alkalotic nephrosis, even if other clinical data are not helpful

*Treatment —Prevention* of alkalotic nephrosis simply involves accurate recording of the volume of vomitus or gastric aspirate frequent checking up on the serum electrolytes especially chloride, bicarbonate, and sodium (the last is essential when the sum of the first two in milliequivalents is abnormally low) and eschewing the use of soluble alkalies as antacids Diet or administered fluids should contain enough sodium chloride to cover all possible losses and restore normal electrolyte balance in the serum Potassium deficits must be restored Food is the ideal vehicle for potassium but slow parenteral infusion of dilute potassium chloride (40 meq/liter) in Ringer s solution is indicated for patients who are vomiting Dehydration must be prevented by adequate fluids to maintain a urine volume of 1500 cc per 24 hours The urea nitrogen and creatinine levels of the blood are determined at frequent intervals Circulatory depletion and hypotension particularly after gastrointestinal bleeding or an operation, are best corrected with blood transfusions Any central nervous system symptoms should be considered possibly alkalotic or hypochloremic in origin until serum analyses prove otherwise Sedatives especially barbiturates and narcotics should not be given excessively if they are much confusion of the clinical picture results Bromides should never be used

*Symptomatic treatment* is essentially etiologic in this syndrome Since in most cases considerable dehydration accompanies the electrolyte loss isotonic saline solution or Ringer s solution with or without added potassium should be given parenterally Prolonged alkalosis severe renal damage persistent oliguria cardiac insufficiency and pulmonary congestion however often make it dangerous to administer over a short period the large volume of fluid necessary to carry in isotonic form the calculated deficit of sodium and chloride Here or when the dehydration is not serious it is quickest and safest to use a slow infusion of molar sodium-chloride solution About half the calculated deficit of salt in the extra

cellular fluids is given at one time and part of the rest later depending on the response of the patient and the results of serum analyses. Half molar ammonium-chloride solution given intravenously is also effective but furnishes no sodium and sometimes causes unpleasant reactions. Whenever the levels of both the serum sodium and the serum chloride are very low, hypertonic solutions of saline are mathematically indicated, as Peters has clearly shown. Only after major restoration of the serum-electrolyte pattern may isotonic solutions be given. Considerable urinary loss of potassium may occur during this restoration process, as well as decrease in the serum level associated with the disappearance of infused glucose from the blood stream. Symptomatic, electrocardiographic and chemical evidence of hypopotassemia should be carefully looked for and corrected. The attempt to lower azotemia by giving large amounts of fluid or intravenous glucose may produce the desired effect through diuresis but further aggravate electrolyte depletion. The diet—if the patient can eat—should at first be low in protein and high in carbohydrate and fat to reduce catabolism to the minimum. If parenteral feeding is necessary, glucose in a concentration of from 5 to 10 per cent is added to the electrolyte solutions. Adequate supplements of vitamins B and C are essential. Surgical relief of pyloric obstruction underlying the patient's alkalosis is deferred until the body fluid and electrolyte imbalance and renal function have improved considerably and the patient's general condition is suitable. This may take weeks of careful medical management.

## HYPERCALCEMIC NEPHROSES

Hypercalcemic nephrosis is found in association with acute or chronic hyperparathyroidism, acute or chronic vitamin D intoxication, rapid osteolytic metastases as a result of carcinoma of the breast (especially when aggravated by testosterone therapy) and in rare instances chronic peptic ulcer with hypercalcemia as a result of excessive ingestion of milk and alkalies containing calcium. The clinical syndrome is usually of an acute type and is often fatal.

*Pathogenesis.*—The pathogenesis of the disturbance is presumably tubular and vascular renal injury due to calcium precipitation. Other important factors are severe hemodynamic changes resulting from the general cardiovascular and neuromuscular effects of hypercalcemia and increased blood viscosity, dehydration from vomiting and anorexia, and the possible toxic action of protein derivatives released from bone matrix during rapid osteolysis. The result is severe renal impairment, oliguria and mounting retention of non protein nitrogen. A vicious cycle is established: the urinary calcium excretion is reduced from previously high levels and the hypercalcemia thereby aggravated. This may occur in spite of the rise in serum phosphate that accompanies the developing uremia. The renal process may end suddenly or gradually recede under treatment, presumably tubular regeneration occurs. But since hypercalcemia is often recurrent or chronic, the continued renal damage, both tubular and vascular, ultimately leads to atrophy of many tubules, interstitial fibrosis and increased calcification. In hyperparathyroidism gross nephrolithiasis is common; this is often complicated by calculous pyelonephritis and often ends in uremia. In other conditions the clinical and pathological data are insufficient to warrant discussion.

*Symptoms and Course.*—The symptoms of hypercalcemic nephrosis usually arise in the course of the underlying disease which may mask them. The most characteristic symptoms are rapidly developing anorexia, nausea, vomiting and acute abdominal pain. Nervous disturbances and marked muscular weakness are associated with symptoms of circulatory collapse. Vomitus and diarrheal stools may contain gross blood. Hemoconcentration may be striking and the blood very viscid or thin. Cyanosis occurs in the severe cases. The urine, at first concentrated and loaded with calcium compounds, is rapidly reduced in volume and becomes isosthenuric. It usually contains protein and often contains erythrocytes but is otherwise nonspecific. The blood's retention of nonprotein nitrogen is marked and the

serum-calcium levels are usually well above 12 mg per 100 cc Often the serum calcium levels rise acutely above previous high levels The inorganic phosphate level of the blood is either normal or elevated Other electrolyte disturbances are common, due to vomiting and diminished intake Circulatory collapse and uremia usually follow in severe or poorly treated cases In mild attacks recovery ensues with re-establishment of renal function and diuresis The pattern of renal dysfunction under an attack of hypercalcemic nephrosis is similar to that caused by any other acute toxic nephrosis but the exact steps in its development are not yet known Return to completely normal function may never occur in patients who otherwise recover Whether this indicates previous renal damage is not clear

*Diagnosis* —Striking gastrointestinal symptoms in a patient known or suspected of having a bone disease associated with hypercalcemia call for examination of the blood and the urine This should lead to a quick diagnosis A history of the patient s use of vitamin-D preparations for arthritis may reveal an important clue X-rays of the chest spinal column pelvis or skull may disclose osteolytic metastases in subjects not known to have primary malignant tumor One must of course consider other causes of abdominal pain and oliguria such as calculous obstruction acute pancreatitis or penetrating peptic ulcer intestinal obstruction Addison s disease and vascular accident No other type of toxic nephrosis is characterized by hypercalcemia

*Treatment* —Early diagnosis of the underlying disease and its appropriate treatment may prevent hypercalcemic nephrosis Hypercalcemia calls for prohibition of milk cheese other calcium foods vitamin D and testosterone and maintenance of a high fluid intake and urine volume There should be frequent check ups on the blood s calcium levels Special caution is indicated whenever a metastasis ridden patient is suddenly immobilized by a fracture or other disability At the slightest sign of gastrointestinal trouble or inability to drink the necessary amount of fluids parenteral hydration should be initiated

*Symptomatic treatment* consists in prompt dilution of the viscous blood by intravenous fluids, free from calcium and sufficient in daily amount to restore extrarenal losses as well as ensure a urinary output of at least 1,500 cc This is on the assumption that the kidney still responds to hydration Electrolyte imbalance or acidosis is corrected in the usual manner Glucose is given freely to reduce protein catabolism and the diet is kept free from protein until renal function improves Intravenous doses of sodium-citrate solution may be given cautiously in the hope of reducing the concentration of calcium ions especially in patients who do not immediately respond with diuresis and are in serious danger of continued calcium precipitation or cardiac damage After recovery patients should stick to the preventive regimen Resumption of testosterone or vitamin-D therapy is exceedingly dangerous In patients whose hyperparathyroidism is first diagnosed as the result of an attack of hypercalcemic nephrosis subsequent parathyroidectomy may be followed by a severe hypocalcemic tetany This requires vigorous calcium mobilizing treatment and the infusion of calcium compounds When hypercalcemic nephrosis occurs as part of a secondary or renal hyperparathyroidism treatment is effective only in so far as the chronically diseased kidneys can respond to the rehydration Since this complication is likely to be associated with a salt-losing type of renal insufficiency adequate intake of sodium preferably as sodium chloride to prevent an alkaline urine is necessary

## THE FUNCTIONAL RENAL DISEASES

The functional renal diseases include first the functional renal impairment of established hypertension with its general arteriolar vasoconstriction congestive heart failure constrictive pericarditis and the acute vascular toxemias of pregnancy second the hemodynamic disturbances associated with a multitude of insults to the body whether of hemolytic traumatic infectious toxic or metabolic origin (in this hemodynamic group the renal func

tional changes are only a brief step removed from the total disorganization resulting in the same kidneys once the organic nephrosis the so-called lower nephron nephrosis takes over in these two subdivisions of functional renal diseases the major etiological factor is *reduction in renal blood flow*) third renal dysfunctions attributable to imbalance of the hormones which normally influence the tubular reabsorption of water and electrolytes and to a lesser extent glucose and uric acid fourth disturbances attributable to such *inborn abnormalities* of renal enzyme pattern as renal diabetes the Fanconi syndrome renal rickets and osteomalacia and lack of capacity for ammonia production fifth *renal tubular enzymatic dysfunctions produced by drugs* (like phlorizine caronamide mercury and sulfanilamide) and dietary protein and sixth *renal venous congestion* or renal venous hypertension This is of vital importance in the common postural or orthostatic proteinuria and in certain phases of the edema of congestive heart failure

## RENAL DYSFUNCTIONS ASSOCIATED WITH RENAL ARTERIOLAR CONSTRICTION

The most important of these dysfunctions are circulatory *shock* acute and chronic *congestive heart failure* (including constrictive pericarditis) established vascular or *essential hypertension* and the acute vascular *toxemias of pregnancy* In all of these renal blood flow is more or less strikingly reduced Glomerular filtration is usually relatively less affected except in shock and in pregnancy Tubular function is variously affected it is normal in cases of early shock and in cases of chronic heart failure of rheumatic origin in younger patients is decreased in cases of hypertensive disease and is severely impaired in cases in the late stages of acute shock The same reduction in renal blood flow and rate of glomerular filtration may be found in both a severely edematous cardiac patient and a perfectly edema free hypertensive patient without heart failure Both may have normal venous pressure and normal plasma protein levels and be on the same salt intake Why the difference in renal excretion of salt? The renal tubules of the patient with heart failure probably are reabsorbing salt normally because presented with less than normal volume of filtrate the glomerulotubular imbalance favors the tubules In the hypertensive patient on the other hand the tubules are no longer normal can no longer normally dissociate salt from water and leak more salt under conditions of water diuresis There is no glomerulotubular imbalance and no edema develops for years in spite of the reduced rate of glomerular filtration Heart failure may of course supervene and further lower the filtration rate and upset the glomerulotubular balance Congestive heart failure is next to myocardial insufficiency a functional disease of the kidneys Functional renal disease is largely responsible for salt retention and cardiac edema Other factors hormonal and metabolic are also implicated in the complex syndrome of congestive heart failure but even some of these extrarenal factors may exercise much of their influence via the renal tubular reabsorptive mechanisms

To the extent that renal arterial and arteriolar constriction sets off tubular enzymatic processes that release vasopressor or vasotropic substances into the general circulation the toxemias of pregnancy are partly—at least in the early stages—renal functional disorders In time of course the organic glomerulonephrosis of pregnancy replaces the purely functional disturbance

The *symptoms* proceeding from renal arteriolar constriction depend on whether the process is acute or chronic and on what the underlying disease is In shock for example oliguria proteinuria concentration of the urine and striking reduction in renal blood flow and the rate of glomerular filtration are evident In chronic congestive heart failure the reduced rate of glomerular filtration and the glomerulotubular imbalance are important renal factors in both the retention of salt and water and the development of dyspnea edema hypervolemia and venous hypertension with their secondary hemodynamic consequences In the toxemias of pregnancy there is often a combination of hypertension edema and

serum-calcium levels are usually well above 12 mg per 100 cc Often, the serum calcium levels rise acutely above previous high levels The inorganic phosphate level of the blood is either normal or elevated Other electrolyte disturbances are common due to vomiting and diminished intake Circulatory collapse and uremia usually follow in severe or poorly treated cases In mild attacks recovery ensues with re-establishment of renal function and diuresis The pattern of renal dysfunction under an attack of hypercalcemic nephrosis is similar to that caused by any other acute toxic nephrosis but the exact steps in its development are not yet known Return to completely normal function may never occur in patients who otherwise recover Whether this indicates previous renal damage is not clear

*Diagnosis* —Striking gastrointestinal symptoms in a patient known or suspected of having a bone disease associated with hypercalcemia call for examination of the blood and the urine This should lead to a quick diagnosis A history of the patient's use of vitamin D preparations for arthritis may reveal an important clue X rays of the chest spinal column pelvis or skull may disclose osteolytic metastases in subjects not known to have primary malignant tumor One must of course consider other causes of abdominal pain and oliguria such as calculous obstruction acute pancreatitis or penetrating peptic ulcer intestinal obstruction, Addison's disease and vascular accident No other type of toxic nephrosis is characterized by hypercalcemia

*Treatment* —Early diagnosis of the underlying disease and its appropriate treatment may prevent hypercalcemic nephrosis Hypercalcemia calls for prohibition of milk cheese, other calcium foods vitamin D and testosterone and maintenance of a high fluid intake and urine volume There should be frequent check ups on the blood's calcium levels Special caution is indicated whenever a metastasis ridden patient is suddenly immobilized by a fracture or other disability At the slightest sign of gastrointestinal trouble or inability to drink the necessary amount of fluids parenteral hydration should be initiated

*Symptomatic treatment* consists in prompt dilution of the viscous blood by intravenous fluids free from calcium and sufficient in daily amount to restore extrarenal losses as well as ensure a urinary output of at least 1500 cc This is on the assumption that the kidney still responds to hydration Electrolyte imbalance or acidosis is corrected in the usual manner Glucose is given freely to reduce protein catabolism and the diet is kept free from protein until renal function improves Intravenous doses of sodium citrate solution may be given cautiously in the hope of reducing the concentration of calcium ions especially in patients who do not immediately respond with diuresis and are in serious danger of continued calcium precipitation or cardiac damage After recovery patients should stick to the preventive regimen Resumption of testosterone or vitamin-D therapy is exceedingly dangerous In patients whose hyperparathyroidism is first diagnosed as the result of an attack of hypercalcemic nephrosis subsequent parathyroidectomy may be followed by a severe hypocalcemic tetany This requires vigorous calcium mobilizing treatment and the infusion of calcium compounds When hypercalcemic nephrosis occurs as part of a secondary or renal hyperparathyroidism treatment is effective only in so far as the chronically diseased kidneys can respond to the rehydration Since this complication is likely to be associated with a salt losing type of renal insufficiency adequate intake of sodium preferably as sodium chloride to prevent an alkaline urine is necessary

## THE FUNCTIONAL RENAL DISEASES

The functional renal diseases include first the functional renal impairment of established hypertension with its general arteriolar vasoconstriction congestive heart failure constrictive pericarditis and the acute vascular toxemias of pregnancy second the hemodynamic disturbances associated with a multitude of insults to the body whether of hemolytic traumatic infectious toxic or metabolic origin (in this hemodynamic group the renal func

tional changes are only a brief step removed from the total disorganization resulting in the same kidneys once the organic nephrosis (the so-called lower nephron nephrosis) takes over. (In these two subdivisions of functional renal diseases the major etiological factor is *reduction in renal blood flow*.) third, renal dysfunctions attributable to imbalance of the hormones which normally influence the tubular reabsorption of water and electrolytes and, to a lesser extent, glucose and uric acid; fourth, disturbances attributable to such *inborn abnormalities* of renal enzyme pattern as renal diabetes, the Fanconi syndrome, renal rickets and osteomalacia, and lack of capacity for ammonia production; fifth, *renal tubular enzymatic dysfunctions produced by drugs* (like phloridzine, caronamide, mercury and sulfanilamide) and dietary protein; and sixth, *renal venous congestion* or renal venous hypertension. This is of vital importance in the common postural or orthostatic proteinuria and in certain phases of the edema of congestive heart failure.

## RENAL DYSFUNCTIONS ASSOCIATED WITH RENAL ARTERIOLAR CONSTRICTION

The most important of these dysfunctions are circulatory *shock*, acute and chronic *congestive heart failure* (including constrictive pericarditis), established vascular or *essential hypertension* and the acute vascular *toxemias of pregnancy*. In all of these renal blood flow is more or less strikingly reduced. Glomerular filtration is usually relatively less affected, except in shock and in pregnancy. Tubular function is variously affected: it is normal in cases of early shock and in cases of chronic heart failure of rheumatic origin in younger patients, is decreased in cases of hypertensive disease and is severely impaired in cases in the late stages of acute shock. The same reduction in renal blood flow and rate of glomerular filtration may be found in both a severely edematous cardiac patient and a perfectly edema free hypertensive patient without heart failure. Both may have normal venous pressure and normal plasma protein levels and be on the same salt intake. Why the difference in renal excretion of salt? The renal tubules of the patient with heart failure probably are reabsorbing salt normally because presented with less than normal volume of filtrate; the glomerulotubular imbalance favors the tubules. In the hypertensive patient, on the other hand, the tubules are no longer normal, can no longer normally dissociate salt from water, and leak more salt under conditions of water diuresis. There is no glomerulotubular imbalance and no edema develops for years in spite of the reduced rate of glomerular filtration. Heart failure may, of course, supervene and further lower the filtration rate and upset the glomerulotubular balance. Congestive heart failure is, next to myocardial insufficiency, a functional disease of the kidneys. Functional renal disease is largely responsible for salt retention and cardiac edema. Other factors, hormonal and metabolic, are also implicated in the complex syndrome of congestive heart failure, but even some of these extrarenal factors may exercise much of their influence via the renal tubular reabsorptive mechanisms.

To the extent that renal arterial and arteriolar constriction sets off tubular enzymatic processes that release vasopressor or vasotropic substances into the general circulation, the toxemias of pregnancy are partly—at least in the early stages—renal functional disorders. In time, of course, the organic glomerulonephrosis of pregnancy replaces the purely functional disturbance.

The *symptoms* proceeding from renal arteriolar constriction depend on whether the process is acute or chronic and on what the underlying disease is. In shock, for example, oliguria, proteinuria, concentration of the urine and striking reduction in renal blood flow and the rate of glomerular filtration are evident. In chronic congestive heart failure the reduced rate of glomerular filtration and the glomerulotubular imbalance are important renal factors in both the retention of salt and water and the development of dyspnea, edema, hypervolemia and venous hypertension with their secondary hemodynamic consequences. In the toxemias of pregnancy there is often a combination of hypertension, edema and

proteinuria How much of the hypertension and the associated cerebral vascular reaction are renal in origin is not clear Nonprotein nitrogen retention occurs in the preceding conditions partly in accordance with reduced glomerular filtration rate which is not counterbalanced by extra intake of fluid to increase the urine volume on a given level of protein catabolism In patients with edema, it is difficult to achieve water diuresis unless salt is restricted

*Treatment* is to be directed toward the *etiologic disease* responsible for the renal hemodynamic alteration The renal dysfunction of shock, for example, is promptly alleviated by proper therapy for shock Restitution of circulating blood volume and lost extracellular fluids and electrolytes relieves the kidney of ischemia by increasing cardiac output and reduces the need for extreme tubular conservation of body water In cases of chronic heart failure, it may be practically impossible (which it is not in cases of acute heart failure) to increase materially the cardiac output the renal blood flow, and the rate of glomerular filtration The best way to deal with cardiac renal dysfunction, therefore is first to reduce the dietary salt intake so that less exogenous salt is retained and second to inhibit tubular reabsorption of salt by means of mercurial diuretics and auxiliary aids (ammonium chloride, aminophyllin) The latter favors the removal of edema fluid in spite of the reduced rate of glomerular filtration Measures that promote reabsorption of the edema fluid into the circulation—such measures as rest, elevation of the legs relief of abdominal or intrapleural pressure due to transudates, and digitalization—are helpful In the toxemias of pregnancy dietary control of sodium intake sedation to subdue excessive vasomotor stimulation and termination of pregnancy to correct the underlying hormonal imbalance are necessary to relieve the serious vascular disturbance of which the renal dysfunction is only one aspect

## HORMONAL RENAL TUBULAR DYSFUNCTIONS

*Diabetes Insipidus* —Diabetes insipidus manifests itself in renal symptoms striking polyuria with very dilute urine secondary thirst delayed response to sudden loads of water or electrolytes, and serum-electrolyte changes resulting from too much or too little sodium or chloride depending on the balance of intake and output

*Adrenal Cortical Disease* —Adrenal-cortical disease may affect renal function seriously either as a result of adrenal-cortical insufficiency (as in Addison s disease) or hyperadrenocorticism (as in the Cushing syndrome due to hyperplasia or neoplasia) It is to be noted that the therapeutic use of ACTH and cortisone may also affect renal function In Addison s disease renal dysfunction is a complex disturbance involving not only reduced blood flow and glomerular filtration but also (and more important) tubular impairment of reabsorption so severe as to bring about marked urinary loss *of sodium and chloride The electrolyte* depletion dehydration and hemoconcentration so produced may rapidly lead to circulatory collapse and accumulation on nonprotein nitrogen

*Cushing Syndrome* —In the Cushing syndrome, renal dysfunction occurs after the early stages filtration decreases the reabsorption of salt and water increases, this leading to diffuse edema Whether the hypertension is also of renal origin has not been determined

## HYPERPARATHYROIDISM

Hyperparathyroidism produces a functional renal disease owing to the action of the parathyroid hormone on tubular reabsorption (of phosphate primarily) the excretion of phosphate and calcium is increased This dysfunction sooner or later leads to calcium phosphate precipitation and to stone formation in the kidney In addition the effect of hypercalcemia on blood viscosity and circulation may produce acute depression of renal blood flow and filtration together with rapid development of azotemia The boundary line between this functional change and hypercalcemic nephrosis is tenuous The *symptoms* are those of the etiologic disease along with polyuria and high calcium *content in the* urine Abdominal pain oliguria nausea

and vomiting are serious danger signals of acute hyperparathyroidism and are soon followed by circulatory collapse and uremic stupor *Treatment* must concern itself with the primary condition in the parathyroids and with attempts to maintain a large urine volume to dilute the calcium and wash out non protein nitrogen and acid radicals

## ENZYMATIC RENAL TUBULAR DYSFUNCTIONS

*Renal Diabetes* —Renal diabetes is inherited The tubular reabsorption of glucose is less than normal and glycosuria occurs at blood-sugar levels below the usual threshhold The chief danger of the glycosuria lies in its being mistaken for the glycosuria of diabetes mellitus In renal diabetes the mechanism for the tubular reabsorption of glucose is impaired possibly because of inadequate phosphorylation the glucose Tm is reduced and rises in the blood glucose levels after meals or even during fasting lead to glycosuria If the glycosuria is severe ketosis may result particularly in children Restrictions of carbohydrates will favor the development of ketosis Mild cases of renal diabetes show no symptoms severe cases show the polyuria and thirst of glycosuria attacks of hypoglycemia and the secondary metabolic effects of lack of carbohydrates

*Treatment* consists in prescribing a diet high in carbohydrate to prevent hypoglycemia and ketosis Insulin is contraindicated There is no known method for increasing the tubular reabsorption of glucose to the normal level

*Fanconi Syndrome* —The Fanconi syndrome is a congenital renal dysfunction characterized by serious disturbance of growth severe rickets and bone deformities ketosis cystinuria and glycosuria There are striking changes in blood and urine The syndrome is due to a defect in the renal tubular reabsorption of phosphate amino acids calcium and glucose and often to impairment of ammonia production as well Organic acid excretion is greatly increased and acidosis results from loss of base Cystine may be deposited in various organs and cystine stones form in the urinary tract The full blown disease is usually seen in children who show severe and resistant rickets hypophosphatemia hypoglycemia, low serum levels of calcium sodium and bicarbonate elevated serum levels of chloride and very low serum levels of amino-acids In adults osteomalacia and the peculiar linear pseudofractures of Milkman s disease are associated with a similar renal defect in the reabsorption of phosphate and the inability to manufacture ammonia The enzymatic difficulty in the kidney is probably related to phosphorylation but the exact nature of the trouble is so far unknown

*Treatment* includes adequate nutrition to replace losses of glucose and amino acids, a high intake of calcium and phosphate and continued administration of sodium citrate or bicarbonate in amounts sufficient to prevent acidosis from urinary loss of base Alkalinization of the urine also prevents cystine precipitation High dosage of vitamin D may be necessary to cure the severe rickets Metabolic balance study is imperative for rational therapy

*Dietary Renal Dysfunction* —Many of the restricted dietary regimens used for renal diseases carry the implication that excess protein salt fat or other nutrient may, in time damage the function or structure of diseased kidneys But there is not good evidence to show that any balanced diet has a deleterious effect on diseased kidneys On the other hand it can readily be shown that glomerular and tubular clearances are reduced by diets low in salt or protein and increased by diets high in protein

*Hypertension of Renal Origin* —Hypertension of renal origin may be interpreted as an enzymatic tubular dysfunction if one believes in the formation and release of renin VEM and other vasoactive substances implicated in the theories of hypertension as resulting from some hypoxic disturbance in renal tubular metabolism On this basis the *treatment* of such hypertension should involve either increasing the oxygen supply or blood flow to the tubules or reducing their metabolic work to a degree compatible with their available oxygen supply The production of renal hyperemia for more than short periods is still an impractical if not unsafe

*proteinuria* How much of the hypertension and the associated cerebral vascular reaction are renal in origin is not clear Nonprotein nitrogen retention occurs in the preceding conditions partly in accordance with reduced glomerular filtration rate which is not counterbalanced by extra intake of fluid to increase the urine volume on a given level of protein catabolism In patients with edema, it is difficult to achieve water diuresis unless salt is restricted

*Treatment* is to be directed toward the *etiologic disease* responsible for the renal hemodynamic alteration The renal dysfunction of shock for example, is promptly alleviated by proper therapy for shock Restitution of circulating blood volume and lost extracellular fluids and electrolytes relieves the kidney of ischemia by increasing cardiac output and reduces the need for extreme tubular conservation of body water In cases of chronic heart failure it may be practically impossible (which it is not in cases of acute heart failure) to increase materially the cardiac output the renal blood flow, and the rate of glomerular filtration The best way to deal with cardiac renal dysfunction, therefore is first to reduce the dietary salt intake so that less exogenous salt is retained and second to inhibit tubular reabsorption of salt by means of mercurial diuretics and auxiliary aids (ammonium chloride aminophyllin) The latter favors the removal of edema fluid in spite of the reduced rate of glomerular filtration Measures that promote reabsorption of the edema fluid into the circulation—such measures as rest, elevation of the legs relief of abdominal or intrapleural pressure due to transudates and digitalization—are helpful In the toxemias of pregnancy dietary control of sodium intake sedation to subdue excessive vasomotor stimulation and termination of pregnancy to correct the underlying hormonal imbalance are necessary to relieve the serious vascular disturbance of which the renal dysfunction is only one aspect

## HORMONAL RENAL TUBULAR DYSFUNCTIONS

*Diabetes Insipidus* —Diabetes insipidus manifests itself in renal symptoms striking polyuria with very dilute urine, secondary thirst delayed response to sudden loads of water or electrolytes, and serum-electrolyte changes resulting from too much or too little sodium or chloride, depending on the balance of intake and output

*Adrenal Cortical Disease* —Adrenal-cortical disease may affect renal function seriously either as a result of adrenal-cortical insufficiency (as in Addison's disease) or hyperadrenocorticism (as in the Cushing syndrome due to hyperplasia or neoplasia) It is to be noted that the therapeutic use of ACTH and cortisone may also affect renal function In Addison's disease, renal dysfunction is a complex disturbance involving not only reduced blood flow and glomerular filtration but also (and more important) tubular impairment of reabsorption so severe as to bring about marked urinary loss of sodium and chloride The electrolyte depletion dehydration and hemoconcentration so produced may rapidly lead to circulatory collapse and accumulation on nonprotein nitrogen

*Cushing Syndrome* —In the Cushing syndrome renal dysfunction occurs after the early stages filtration decreases, the reabsorption of salt and water increases, this leading to diffuse edema Whether the hypertension is also of renal origin has not been determined

## HYPERPARATHYROIDISM

Hyperparathyroidism produces a functional renal disease owing to the action of the parathyroid hormone on tubular reabsorption (of phosphate primarily) the excretion of phosphate and calcium is increased This dysfunction sooner or later leads to calcium phosphate precipitation and to stone formation in the kidney In addition the effect of hypercalcemia on blood viscosity and circulation may produce acute depression of renal blood flow and filtration together with rapid development of azotemia The boundary line between this functional change and hypercalcemic nephrosis is tenuous The *symptoms* are those of the etiologic disease along with polyuria and high calcium content in the urine Abdominal pain oliguria nausea

an intravenous pyelogram should be made to exclude congenital renal anomalies, hydronephrosis or other lesions in which a postural increase of ordinarily slight proteinuria may be present.

*Treatment* involves complete reassurance of the patient or his parents as to the absence of organic renal disease.

*Cardiac Renal Dysfunction.*—Cardiac renal dysfunction is partly due to decreased renal blood flow secondary to diminished cardiac output and partly to renal venous congestion secondary to general venous hypertension. While acute rise in renal venous pressure of even moderate degree causes an acute reduction in urine volume and salt excretion, it is not established that persistent renal venous hypertension is an important factor in the salt retention and edema of chronic heart failure. It is difficult to prove this in heart failure, for both arterial inflow and venous outflow from the kidneys are abnormal. On the other hand, the edema associated with bilateral renal vein thrombosis is not a pure example either, because of the marked proteinuria and hypoproteinemia. The *treatment* of renal venous congestion in heart failure is obviously included in the management of heart failure *per se*.

## CONGENITAL MALFORMATIONS OF THE KIDNEYS

Anomalies of development of the kidneys are fairly common if minor variations are included. There are anomalies of position (malrotation or pelvic kidneys), of fusion (horseshoe kidney), of reduplication (double pelves or double kidneys), of vascular branching and course (producing constriction of the uretero-pelvic junction and hydronephrosis), of maturation of nephrons (giving rise to single or multiple cysts and the important variety of polycystic kidneys), of obstruction (due to stenosis, valves or neurologic anomalies). Complete agenesis or absence of one kidney may occur or marked hypoplasia on one side and compensatory hypertrophy of the other kidney. There may be bilateral hydronephrotic atrophy of the kidneys which is associated with idiopathic dilatation of the ureters and is commonly the background of renal dwarfism or renal rickets in late childhood or early adult life. Many of the anomalies involving hydronephrosis or atrophic kidney are sooner or later complicated by pyelonephritis.

## POLYCYSTIC KIDNEYS

Polycystic kidneys are, from the medical standpoint, the most important congenital disease of the kidneys because of the varied symptomatology, the long duration in many cases, the familial incidence and the diagnostic and therapeutic problems. While often associated with other anomalies of development, such as cysts in the liver or pancreas and cerebral vascular defects or aneurysms, the course of the disease is essentially dependent on the rate of development of renal insufficiency. This may be very slow and permit survival to the seventh decade or later.

*Etiology and Pathogenesis.*—Polycystic kidneys have a high familial incidence and are undoubtedly a hereditary anomaly. Careful study of the kidneys of lower vertebrates and mammals at different stages of development has led to the view that primitive tubules in the pronephric and mesonephric stages may fail to undergo complete atrophy in preparation for the later metanephros and that the continued secretion into the lumina of these blind tubules produces the cysts. Once cysts are formed, pressure atrophy of intervening normal nephrons gradually develops; this is compensated for by hypertrophy of the less affected nephrons. Distortions of vascular supply and lymphatic drainage, obstruction to urine flow down the collecting ducts or calyces and other difficulties are readily understood. Hemorrhage into cysts and infection or suppuration are common. The kidneys enlarged by the growth of innumerable cysts and hydronephrosis may reach enormous size (25 to 30 cm.) and weight (1 kilo each) and lead to abdominal distention and pressure on adjacent structures. Hypertension and renal insufficiency, usually without edema, are regular consequences. Death results from uremia or cardiovascular disease.

procedure The second alternative is the theoretical basis for the Kempner rice-diet treatment

*Drug Effects* —Drug effects on tubular functions are illustrated in the glycosuria produced by phlorhidzin which inhibits the tubular reabsorption of glucose in the salt- and water diuresis produced by organic mercurials in the phosphate and calcium diuresis caused by parathyroid hormone and in the caronamide inhibition of tubular excretion of penicillin The prevention of mercurial diuresis by BAL (dimercaptopropanol) is a striking example of protection of cellular enzymes by dithiol blocking of a heavy metal There are undoubtedly many other examples of drug induced functional renal disturbances including the self-depression of extraction by the tubules of diodrast p aminohippurate and phenol red by high blood levels of these compounds

## RENAL DYSFUNCTIONS DUE TO RENAL VENOUS CONGESTION

### Postural Proteinuria

Postural proteinuria or orthostatic albuminuria is the most important example of the role of venous congestion in producing a functional renal disease of major diagnostic significance This condition is found at some time or another in the majority of children especially during the rapid growth periods and in the early military ages However it may be observed even through the third and early fourth decade in persons with an asthenic build or poor posture The proteinuria is characteristically produced when the person stands up, especially if he is lordotic The albuminuria disappears when the patient lies down or is in the kyphotic posture The proteinuria almost entirely serum albuminuria, may vary from a trace to four plus although the total 24 hour loss rarely exceeds a few grams Hyaline and granular cylindruria and on occasion excess microscopic hematuria may occur Renal function blood pressure and general health are unimpaired even after years or decades of postural proteinuria The chief damage done by the disease is the anxiety created in the minds of the parents who are fearful of Bright s disease In adults the condition is a major nuisance when it is discovered during an insurance examination and leads to the rejection of the applicant

The *pathogenesis* of lordotic proteinuria has been variously ascribed to renal arterial or arteriolar constriction low pulse pressure and pressure of the lordotic spine on the left renal vein, which must cross over to the right However it has recently been clearly demonstrated by Bull that postural proteinuria is always lordotic in origin occurring even in the recumbent lordotic position and that it is bilateral and is regularly associated with a marked increase in venous pressure in the inferior vena cava below the liver—therefore also in the renal veins This venous congestion is apparently brought about by torsion of the liver on its axis with partial obstruction of the inferior vena cava, which is intimately related to its lower surface It can be reproduced by appropriate manipulation of the liver In addition to renal venous congestion renal blood flow, rate of glomerular filtration, urine volume and salt excretion, decrease sharply when the patient is in the abnormal posture

*Diagnosis* depends on establishing an exact relationship between the posture and the proteinuria Renal function tests and blood pressure should be entirely normal and the history negative for recent acute nephritis or pyelonephritis It may be difficult to obtain an entirely negative sample of urine even while the patient is lying down Nevertheless all specimens of urine must be obtained while the patient is in bed The striking increase in proteinuria during the active period of the day does not of itself distinguish this type of proteinuria from that of organic renal disease On the other hand the absence of protein red cells and casts in a highly concentrated night urine is of decisive diagnostic value The simplest office procedure is to give the subject a glass or two of water to provide urine during the test ask him to empty the bladder before and after 15 minutes of extreme lordosis then after 15 minutes of standing in kyphotic posture and again after 15 or 30 minutes of recumbency in kyphosis Only the first urine specimen should contain protein or formed elements In case of slightest doubt

struction in the abdomen complicates the situation Hypoproteinemia is rare in this disease Accurate renal clearances cannot be carried out because of the obstructive nature of the lesions The renal impairment is manifested in the usual urinary and blood-chemical changes and presents no specific pattern Hypertension is moderate in the earlier decades but later may achieve high levels of both systolic and diastolic pressure and in rare cases take on the aspect of malignant hypertension with all the typical cerebral retinal and cardiac manifestations Practically all adult patients with polycystic kidneys will show hypertension of some degree when the diagnosis is first made

*Diagnosis* —The association of hypertension urinary changes or any signs of renal impairment with palpable enlarged and often irregularly nodular kidneys at any age should warrant a strong suspicion of polycystic kidneys A family history of the disease is highly significant Certain diagnosis is achieved by means of intravenous or retrograde pyelography This will demonstrate the large kidneys the striking crescentic or arciform distortion and elongation of the calyces by the larger cysts and deformity or enlargement of the pelves Practically no other condition simulates this picture During an attack of hematuria in patients whose kidneys are not readily palpated the possibility of renal calculus tumor tuberculosis or nephritis must be considered and in these cases pyelography is the only way to make the diagnosis In patients with chills fever and pyuria the differential diagnosis of pyelonephritis and its background is involved At times bilateral hydronephrosis may be somewhat difficult to distinguish from polycystic kidneys Unilateral polycystic kidney may present a hard problem in diagnosis one that cannot be resolved except by surgical exploration Bilateral kidney tumors of malignant type especially in children may cause diagnostic confusion

*Treatment* —In the asymptomatic cases or those with only occasional hematuria no specific treatment is necessary until renal insufficiency or hypertensive symptoms become manifest Severe hematuria may require blood transfusions to counteract anemia Infections of the cysts are treated with antibiotics early, in the hope of preventing actual suppuration If there are signs of abscess formation exposure of the kidney and drainage of the particular cyst may be necessary Aspiration of accessible large cysts has been carried out with relief or pressure on the renal pelvis but this involves a definite risk when done without direct exposure of the kidney Surgical cauterization of the surface cysts is of value in special cases By and large however treatment should be conservative unless pelvic or ureteral obstruction, severe bleeding or suppurative infection results The hypertensive syndrome is managed largely from the standpoint of preventing cardiac failure or cerebral vascular strain Pregnancy should be discouraged in view of the hereditary nature of the disease However unless the kidneys are large enough to interfere with labor or considerable renal impairment exists there is no reason for terminating a pregnancy

## NEPHROLITHIASIS

Nephrolithiasis may affect any age group it is often associated with acute or chronic pyelonephritis

*Etiology and Pathogenesis* —The basic causes of precipitation of urinary solutes are still a matter of speculation but it is well established that in addition to the purely physicochemical factors of the solubility of calcium phosphate carbonate or oxalate magnesium phosphate uric acid and cystine supersaturation aided by various organic colloids in the urine and the tendency to precipitation of inorganic or organic solutes around a nidus of material (which may be necrotic tissue or a plaque in a renal papilla exudate blood clot foreign body) are etiologically important Once the initial precipitation occurs succeeding deposits of crystals may take place from supersaturated urine at appropriate pH The organic matrix of core of the calculus may begin in the kidney itself as a result of infection other inflammation or degeneration or develop in the lumen of a collecting duct from unknown causes Factors predisposing to stone formation are well known—metabolic

*Symptoms and Course* —If polycystic kidneys are large at birth, death may result from difficulties during delivery or shortly after from renal insufficiency In most cases, marked enlargement does not occur or is not detected for years There need be no symptoms whatsoever, and growth and development may be entirely normal A routine physical examination may reveal bilateral abdominal masses identifiable as Pregnancy or an abdominal operation may also reveal the presence of polycystic kidneys In some patients with such kidneys, the first "symptoms" may be unexplained anemia, weakness, hypertensive encephalopathy, or frank uremia

The *course* of the congenital disease usually lasts for four or five decades in patients fortunate enough to have had good renal function throughout childhood The

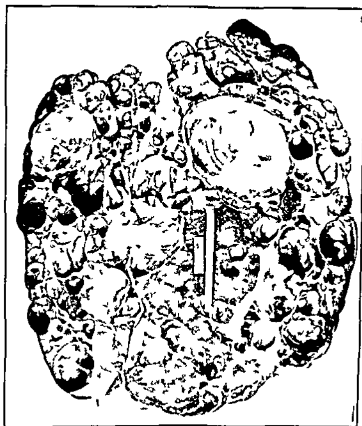

Fig 164

Fig 165

Fig 164 —Large polycystic kidney in sagittal section Note large areas of persisting parenchyma at the center and a few small areas elsewhere (Bell s Renal Diseases )

Fig 165 —Subclinical polycystic kidney Note large areas of persisting parenchyma This lesion did not cause uremia (Bell s Renal Diseases )

kidneys The young patient may come to the physician s attention because of an enlarged abdomen vague pains mild or severe hematuria renal colic without other signs of nephritis loin pain or chills and fever with or without pyuria In the older patient hypertension may be the first finding to lead to investigation of the kidneys Proteinuria is another sign that may first arouse suspicion of polycystic kidney course is often punctuated by attacks of pyelonephritis or suppuration in cysts and hemorrhages into the upper urinary tract with severe renal colic as blood clots are forced down the ureter These episodes may cause the patient considerable misery It is remarkable however how comfortable the patient may be for years despite very large kidneys Edema practically never occurs unless heart failure or venous ob

not developed The serum levels of calcium phosphate and phosphatase are normal unless the patient has parathyroid hyperfunction

*Diagnosis* —In any patient with lumbar pain renal colic proteinuria hematuria pyuria or general symptoms of urinary tract obstruction or infection nephrolithiasis must be seriously considered The same applies to attacks of abdominal pain nausea or vomiting or disturbance in bowel action not readily explained by specific gastrointestinal disease Patients suffering with paraplegia or acutely immobilized by fractures should be considered potential kidney stone patients In children with congenital metabolic disturbances in which cystinuria may occur kidney stones are likely to develop Renal insufficiency unexplained on other obvious grounds and osteoporosis or fibrocystic disease of bones should lead the physician to search for kidney stones With the exception of uric acid and cystine calculi kidney stones of significant size are radiopaque because of their calcium content Hence *x* ray studies preferably in the form of pyelography are most useful Differential diagnosis is chiefly concerned with distinction between kidney stones and other calcific shadows particularly gallstones and calcified mesenteric nodes or vascular lesions Careful analysis of the patient s history the physical and urinary findings and the *x* ray studies will usually clear up the situation The distinction between calculous disease of the kidneys and other renal diseases especially tuberculosis tumor or noncalculous pyelonephritis is ordinarily not difficult to make unless there are nonopaque or indefinitely outlined calculi Special diagnostic studies—cultures and inoculation of urinary sediment for tuberculosis and special staining of smears for neoplastic cells—prove helpful

*Treatment* —When a renal calculus is causing no trouble no specific treatment is necessary except for attempts to prevent further stone formation This *preventive* therapy however can be based intelligently only on a knowledge of the nature of the precipitated material Therefore a systematic chemical analysis should be made of any stone passed The type of stone can be determined with some accuracy from the density and morphological character of the calculus on the *x* ray films from the predisposing factors to stone formation in a given patient and from the finding of excess or abnormal crystals in freshly voided urines especially during periods of microscopic hematuria In the case of calcium phosphate or carbonate stones a high fluid intake and high urine volume (3 liters daily) must be maintained to reduce the calcium ion concentration At the same time the diet should be low in calcium especially in milk and cheese but high in vitamin A An acid urine (pH 5 2 to 5 4 and checked daily) should be maintained by an acid ash diet amplified by acid forming salts or ammonium mandelate For oxalate stones foods rich in oxalates (rhubarb beets spinach cocoa) should be restricted The urine should be kept slightly acid In the case of uric acid stones the opposite regimen—an alkaline ash diet moderately low in purine with alkalinizing salts to keep urates in solution—is employed Cystine is also held in solution by alkaline regimens In paraplegics and patients immobilized by casts or prolonged severe arthritis or ulcerative colitis with marked malnutrition frequent change of position to favor drainage from all parts of the renal pelves and close attention to diet and fluid intake to lower the calcium concentration and excretion in the urine are very important measures The same dietary regimen applies to patients exposed to subtropical desert climates that induce oliguria and large extrarenal losses of water Under these conditions renal calcium deposits have been observed to form within a matter of weeks if the diet and local water supply happened to be rich in calcium

The chief effects of nephrolithiasis are infection—pyelonephritis—and urinary tract obstruction (which in turn predispose to further stone formation by tissue destruction changes in urinary pH and production of stagnant urine saturated with poorly soluble crystalloids) these two sequela must be treated vigorously Unfortunately in the presence of stone and urinary obstruction infection is difficult to eradicate even with antibiotics and regularly recurs Resistant bacterial strains soon develop (*v*

disorders, such as cystinuria, oxaluria, gout or hyperparathyroidism, obstruction or stasis in the urinary tract and immobilization with its effects on the bones and the urinary calcium excretion as in paraplegics, low fluid intake and alkaline ash diets high in calcium and low in protein such as are common in tropical and subtropical regions, vitamin A deficiency with its metaplastic action on urinary tract epithelium and some sort of constitutional tendency to stone formation. The etiology of nephrolithiasis varies therefore with the type of stone found and is often complex.

Once the nucleus of a stone has developed in one or more sites in the kidney, the process goes on until the stone reaches a certain size at which it may then remain stationary for years. Local pressure atrophy of parenchyma and fibrosis occur but the major results are obstruction of some part of the calyceal system with dilatation proximal and soil favorable for infection or calculous pyelonephritis. Pressure erosion of local vessels often leads to bleeding. Pieces of a calculus may break away from the surface and pass on into the renal pelvis and ureter to produce colic, bleeding or obstruction, with or without infection. A stone originating in the pelvis may reach a large size with branching finger-like projections into the calyces—(the staghorn calculus). When the disease is bilateral sufficient destruction of parenchyma may result to produce severe renal insufficiency. Small stones may be passed repeatedly and new ones form over a period of years. In the case of uric acid calculi precipitates of urates may occur in masses throughout the pyramids and renal papillæ and give rise to the so-called uric acid infarcts.

*Symptoms and Course.*—The presence of nephrolithiasis may be entirely unsuspected for years. Sometimes incidental x-ray studies for gastrointestinal or vertebral column disease first reveal kidney stones; sometimes the finding of microscopic hematuria or pyuria during routine examinations first leads to an investigation of the urinary tract. Lumbar backache or abdominal distress at times precipitated or aggravated by activity associated with considerable jolting such as accompanies horseback riding or long motor trips over poor roads may be the presenting symptoms. The classical attack of acute renal colic is characterized by hematuria and vomiting or abdominal distention and constipation, and severe tenderness and spasm over the affected kidney or overlying abdominal wall. Symptoms of acute or chronic low grade pyelonephritis may be the only evidence of nephrolithiasis until x-ray and other urologic studies are made; recurrent gross hematuria may be the only symptom for years. Various gastrointestinal symptoms including the syndrome of spastic or irritable bowel, may lead the patient to one physician after another before the kidney stones are discovered. Patients with hyperparathyroidism may not be recognized as having either the primary parathyroid disease or the secondary nephrolithiasis till symptoms of the pre-uremic state appear. Nephrolithiasis may be associated with hypertensive disease, gouty arthritis, neurologic abnormalities and other conditions depending on the underlying or complicating disorder and the age of the patient.

The *urine* may be entirely negative but will usually show traces of proteinuria and microscopic hematuria. Excess leukocytes without casts will also usually be found in the urine. Crystals of the stone-forming material may be present in increased amounts but this is difficult to interpret unless substances like cystine, normally absent from the urine, are detected. Gross hematuria will occur during attacks of colic or even in pain-free intervals. The urine may be loaded with leukocytes and urea-splitting bacteria during periods of infection or as a persistent process when stones extend into the renal pelvis. The amount of protein in the urine is usually small, not more than one would expect from the quantity of blood in the sediment. The concentration of the urine may be entirely normal in many cases but will reflect renal impairment or obstruction in others. In about half the cases of calcium stones the Sulkowitch test usually reveals excessive calcium concentration in the urine even when the diet is low in calcium.

The *blood chemistry* is usually not altered in nephrolithiasis if renal impairment has

and hemorrhage followed by cholesterol and calcium precipitation are very frequent in malignant renal tumors and give rise to irregular or continuous fever leukocytosis and other general symptoms The neurogenic tumors metastasize readily into the liver the lungs and remarkably the cranial bones of the orbital wall in children Displacement of abdominal organs and distortions of the pelvis and ureter are common results of large renal tumors

*Symptoms and Course*—Even tumors of some size may be asymptomatic in the renal cortex Symptoms arise when the tumor reaches the pelvis and bleeds ulcerates or causes local obstruction Ordinarily painless hematuria is an early symptom This may be slight or massive intermittent or continuous Dull pain in the flank pain *often radiating into the abdomen may* appear early or late A mass is often palpable especially in the more accessible right kidney Low intermittent fever or prolonged pyrexia is seen in patients with urinary tract infection or large tumors undergoing necrosis Hemorrhage into the perirenal tissues may give rise to acute abdominal pain vomiting and other signs of peritoneal irritation The patient may have no obvious renal symptoms but general malaise fatiguability weight loss anemia moderate leukocytosis and an elevated erythrocyte-sedimentation rate In some patients the first symptom of a hypernephroma may be a varicocele or hydrocele due to invasion by tumor or thrombosis of the spermatic vein especially on the left In others pathological fracture of a long bone or accidental *x* ray demonstration of an osteolytic lesion in the skull or a pulmonary metastasis first suggests renal carcinoma Symptoms of cerebral metastasis may also give the first clue In children enlargement of the abdomen is an important sign of rapidly growing tumors The kidney may or may not be tender or enlarged in patients with renal tumors Obviously the small tumors will produce no local physical signs The larger growths may reflect themselves in hydronephrotic or irregular nodular kidneys mobile or fixed In advanced cases of malignancy both kidneys may be involved and signs of occlusion of the inferior vena cava—edema of the legs scrotum and lower back collateral veins hemorrhoids—may be prominent In these cases chemical evidence of renal impairment can be elicited

The urine may be normal in cases of parenchymal renal tumor of small size Ordinarily, hematuria of varying degree pyuria (in case of secondary infection or ulceration) albuminuria not disproportional to the bleeding (except when the renal vein is thrombosed) and in a limited number of cases conglomerates of tumor cells in the urinary sediment may be expected The cystoscopic and urographic examinations will demonstrate unilateral bleeding and renal pelvic abnormalities in the form of caliceal distortion elongation or obliteration filling defects hydronephrosis or enlargement of the affected kidney Perirenal hemorrhage *may obliterate the iliopsoas muscle s shadow* In some early cases even after careful and repeated *x* ray studies to explain the unilateral hematuria nothing abnormal can be found and only surgical exploration of the kidney will disclose the tumor

*Prognosis*—The prognosis varies with the type of malignant tumor the time of its recognition and the presence or absence of venous invasion or metastases About 20 per cent of nephrectomized adult patients survive 5 years The outlook for children with rapidly growing embryonal tumors is much less hopeful

*Diagnosis*—The chief diagnostic problem is simply recognizing the presence of renal tumor The differential diagnosis therefore concerns the numerous causes of hematuria In the absence of urinary or general clinical signs of bilateral renal disease or blood dyscrasia prompt cystoscopic and urographic examinations are indicated Renal tuberculosis must be ruled out if the tumor is not large enough to produce typical *x* ray findings Nonopaque calculi may create confusion in the absence of attacks of renal colic In all cases suspected of renal tumor the chest and skull also should be *x* rayed Patients with brain tumors may be suffering from metastases from primary renal malignancy Patients with unexplained fever weight loss and anemia who are in the high frequency decades for cancer should be given urologic diagnostic study

"Pyelonephritis") The urea-splitting organisms (e g, staphylococci and B proteus) are a particularly tough problem, for the alkaline reaction they cause strongly favors calcium and magnesium precipitation Obviously the vicious circle can only be broken by surgical therapy of the nephrolithiasis The stone may be removed, a portion of the kidney resected or complete nephrectomy carried out In recent years, there has been a strong tendency to preserve as much of the kidney as possible by appropriate plastic procedures If the kidney stones are secondary to parathyroid tumor or hyperplasia the surgical treatment should be directed early to the parathyroid in order to stop the hypercalcemia and the continued precipitation of calcium salts in the kidney If large or multiple renal calculi extend into the pelvis or surgery is contraindicated because of bilateral renal involvement renal insufficiency or the patient's general condition the use of irrigating solutions via ureteral catheter or nephrostomy tube may be tried This procedure has been successful in enough cases to warrant further trial under careful urologic control The solutions vary in composition but generally contain citric acid magnesium citrate and sodium carbonate and yield a pH of 4 2 (tolerated by the mucosa of the urinary tract)

## RENAL NEOPLASMS

Neoplasms of the kidney include a variety of benign and malignant tumors the latter generally occurring in persons over 40 though the neurogenic tumors and the highly malignant embryonal adenomyosarcoma (Wilms tumor) are found in infants and young children Painless hematuria is a common symptom but the clinical picture varies with the location the rate of growth and the nature of the extension of the tumor

*Classification* —Renal neoplasms originate in the parenchyma in 80 or 85 per cent of the cases and in the pelvis in about 15 per cent Neoplasms rarely originate in the capsule of the kidney The *parenchymal* tumors are, with few exceptions malignant the majority being carcinomas (hypernephromas or Grawitz tumors) of the alveolar papillary, or tubular variety Papillary cystadenomas or carcinomas also occur either singly or in multiple form in fibrotic kidneys Highly malignant mixed tumors or carcinosarcomas occur in adults Wilms tumor is the counterpart in infants True adrenal rest tumors are very rare but when found, are usually located near the capsule

*Tumors of the renal pelvis* are either papillary or epidermoid and are of the squamous-cell type If epidermoid they are often associated with calculus or with epithelial tumors in the lower urinary tract

*Tumors of the renal capsule* usually consist of lipomas fibromas or corresponding sarcomas

*Etiology and Pathogenesis* —The incidence of renal neoplasms is more than twice as high in males as it is in females Though the most common malignant renal neoplasms in adults the hypernephromas were originally believed to originate in adrenal-cortical rests these tumors are now known to arise from renal tubular epithelium The adenomyosarcomas of children are considered to be either teratomatous or embryonal nephrogenic in origin No known urinary constituent has ever been shown to be neoplastogenic but one must remember the continuous excretion of a host of steroid compounds of hormonal and other metabolic origin There is no evidence of an industrial origin for kidney tumors as there is for bladder tumors among aniline dye workers A renal neoplasm may exert pressure on surrounding renal tissue or a calyx and cause local obstruction Invasion of veins by hypernephromas and other renal tumors is very common and leads to thrombosis hemorrhage and necrosis as well as to eventual metastases of the lungs bones and other structures If the tumor breaks into the pelvis ulceration bleeding obstruction and infection soon occur and may present the first gross signs of disease Invasion of the kidney capsule and perinephric fat is a late stage of malignant renal tumors The adrenal gland may be surrounded by the tumor mass Renal venous tumor thrombosis may cause infarction of the kidney or extend into the inferior vena cava and the opposite renal vein to produce the usual signs of major venous obstruction Necrosis

and hemorrhage, followed by cholesterol and calcium precipitation are very frequent in malignant renal tumors and give rise to irregular or continuous fever leukocytosis and other general symptoms The neurogenic tumors metastasize readily into the liver the lungs and remarkably the cranial bones of the orbital wall in children Displacement of abdominal organs and distortions of the pelvis and ureter are common results of large renal tumors

*Symptoms and Course*—Even tumors of some size may be asymptomatic in the renal cortex Symptoms arise when the tumor reaches the pelvis and bleeds ulcerates or causes local obstruction Ordinarily, painless hematuria is an early symptom This may be slight or massive, intermittent or continuous Dull pain in the flank pain often radiating into the abdomen may appear early or late A mass is often palpable especially in the more accessible right kidney Low intermittent fever or prolonged pyrexia is seen in patients with urinary tract infection or large tumors undergoing necrosis Hemorrhage into the perirenal tissues may give rise to acute abdominal pain vomiting and other signs of peritoneal irritation The patient may have no obvious renal symptoms but general malaise fatiguability weight loss anemia moderate leukocytosis and an elevated erythrocyte sedimentation rate In some patients the first symptom of a hypernephroma may be a varicocele or hydrocele due to invasion by tumor or thrombosis of the spermatic vein especially on the left In others pathological fracture of a long bone or accidental x ray demonstration of an osteolytic lesion in the skull or a pulmonary metastasis first suggests renal carcinoma Symptoms of cerebral metastasis may also give the first clue In children enlargement of the abdomen is an important sign of rapidly growing tumors The kidney may or may not be tender or enlarged in patients with renal tumors Obviously the small tumors will produce no local physical signs The larger growths may reflect themselves in hydronephrotic or irregular nodular kidneys mobile or fixed In advanced cases of malignancy both kidneys may be involved and signs of occlusion of the inferior vena cava—edema of the legs, scrotum and lower back, collateral veins hemorrhoids—may be prominent In these cases, chemical evidence of renal impairment can be elicited

The urine may be normal in cases of parenchymal renal tumor of small size Ordinarily, hematuria of varying degree pyuria (in case of secondary infection or ulceration) albuminuria not disproportional to the bleeding (except when the renal vein is thrombosed), and in a limited number of cases conglomerates of tumor cells in the urinary sediment may be expected The cystoscopic and urographic examinations will demonstrate unilateral bleeding and renal pelvic abnormalities in the form of caliceal distortion elongation or obliteration filling defects hydronephrosis or enlargement of the affected kidney Perirenal hemorrhage may obliterate the iliopsoas muscle s shadow In some early cases even after careful and repeated *x* ray studies to explain the unilateral hematuria nothing abnormal can be found and only surgical exploration of the kidney will disclose the tumor

*Prognosis*—The prognosis varies with the type of malignant tumor the time of its recognition and the presence or absence of venous invasion or metastases About 20 per cent of nephrectomized adult patients survive 5 years The outlook for children with rapidly growing embryonal tumors is much less hopeful

*Diagnosis*—The chief diagnostic problem is simply recognizing the presence of renal tumor The differential diagnosis therefore concerns the numerous causes of hematuria In the absence of urinary or general clinical signs of bilateral renal disease or blood dyscrasia prompt cystoscopic and urographic examinations are indicated Renal tuberculosis must be ruled out if the tumor is not large enough to produce typical *x* ray findings Nonopaque calculi may create confusion in the absence of attacks of renal colic In all cases suspected of renal tumor the chest and skull also should be *x* rayed Patients with brain tumors may be suffering from metastases from primary renal malignancy Patients with unexplained fever weight loss and anemia who are in the high frequency decades for cancer should be given urologic diagnostic study

the hope being that operable renal tumors may be detected In children suspected of having Wilms tumor preoperative radio therapy may lead to rapid decrease in the size of the tumor and furnish a diagnostic aid Lymphoblastomatous infiltration of the kidneys may cause confusion in diagnosis but such infiltration is usually bilateral and rarely produces renal symptoms without other clinical signs of lymphomatous disease Renal bleeding due to varices in the pelvis or other vascular lesions may cause considerable difficulty in differential diagnosis, especially when clots in the pelvis produce filling defects Repeated examination is of value in case of doubt exploration alone is certain

*Treatment* —Treatment of renal neoplasms is surgical Radiotherapy may be a useful adjunct however in the management of certain embryonal tumors in children and in lymphomatous involvement of the kidneys

# Diseases of Blood Vessels and Lymph Vessels and Abnormalities of Blood Pressure

By IRVING SHERWOOD WRIGHT M D and CHARLES D MARPLE M D

## THE ANATOMY AND PHYSIOLOGY OF THE BLOOD VESSELS

THE aorta is a wide thick walled tube, the coats of which are rich in elastic tissue When the heart expels blood at high pressure during ventricular systole, the aortic pressure rises The aorta is distended and so accomodates a large portion of the blood expelled from the heart the remainder escaping through the systemic arteries During ventricular diastole the tension exerted by the elastic walls of the aorta maintains the flow of blood onward into the arteries and the aorta diminishes in size until it is distended by the next heart beat Thus the aorta and its larger branches which are similar in structure convert the intermittent output from the heart into the continuous though pulsating flow in the arteries

The arteries into which the blood flows from the aorta divide repeatedly With each subdivision the arterial lumen becomes smaller and the arterial wall becomes relatively more muscular By the contraction or relaxation of these muscular walls the arteries particularly the smaller branches or arterioles, are capable of great variation in caliber It is this variation that determines the proportion of the cardiac output distributed to the various organs

The finest branches of the arterioles are the capillaries, which consist of a single layer of endothelial cells It is through the walls of the capillaries that the interchange of substances between the blood and the tissue spaces takes place

By reason of single muscular elements the capillaries possess the property of independent contractility, mediated by vasoconstrictor nerves and by local chemical or hormonal action The capillaries open and close according to the metabolic needs of the particular tissue in which they lie they react to chemical substances released during the activity of these tissues In resting tissues the capillaries are apt to be almost (or completely) closed during activity they are open Along with the tone of the precapillary arterioles the status of the capillaries determines both the distribution of the blood to the organs and the peripheral resistance

Blood from the capillaries passes through the venules to the systemic veins in which it returns to the heart The veins are large have thinner walls and are less muscular than the arteries They offer little resistance to the flow of blood They are capable of constricting or relaxing in response to vasomotor control They contain valves which prevent a retrograde flow of blood away from the heart Contraction of skele

tal muscles around the veins assists in forcing the blood on its way to the heart When the muscles relax the tension on the veins is relieved and blood flows freely from the arterial side of the circulation toward the heart The action of the skeletal muscles is an important mechanism for facilitating the venous return to the heart and for increasing the output of the heart during exercise

### Factors Determining the Arterial Blood Pressure

The general arterial pressure is determined by the cardiac output and the peripheral resistance The former depends on the venous return to the heart and this in turn on the relationship between the total blood volume and the capacity of the circulatory bed

The peripheral resistance is largely determined by the diameter of the smaller arteries and arterioles and to a lesser extent, the capillaries It is in these vessels that the greatest fall in pressure occurs The state of contraction or tone of the peripheral vessels is controlled by the vasomotor nerves and by the action of certain chemical substances released generally into the circulation or locally from the active tissues Blood viscosity is also a factor in determining peripheral resistance

### The Nervous Control of the Blood Vessels

This is chiefly effected through the autonomic nervous system The sympathetic fibers are adrenergic, the parasympathetic fibers cholinergic and the two have inverse actions on the vessels In the regulation of vascular tone however the sympathetic fibers are by far the more important Stimulation of sympathetic fibers produces vasoconstriction but the degree of constriction varies in different organs The arteries are affected more than the veins or the capillaries It is apparent that there is a steady stream of vasoconstrictor impulses passing along the intact sympathetic fibers since section of these fibers results in an increase of the blood flow through the organ supplied by them Vasodilator impulses transmitted by the sympathetic and parasympathetic systems are of secondary importance

Vasomotor tone is maintained through the mediation of a vasomotor center in the medulla in the floor of the fourth ventricle Stimulation of this area results in generalized vasoconstriction and a rise in blood pressure Section of the brain below this level leads to generalized vasodilatation and a fall in blood pressure The activity of this center in maintaining vasomotor tone is modified by the influence of afferent impulses arising from receptors in the vascular system by impulses from the cerebral hemispheres and by chemical stimuli as for example, by hypercapnia and anoxia

Simple vasodilatation in any organ lowers the peripheral resistance and hence the arterial pressure and increases the capacity of the circulation thus reducing the venous return to the heart and consequently the cardiac output Uncompensated and extensive vasodilatation produces irreversible peripheral circulatory failure or shock Ordinarily this situation is prevented by the compensatory mechanism of the vasomotor reflexes by which vasodilatation in one part of the body is compensated for by vasoconstriction elsewhere Two of these vasomotor reflexes are constantly in action to ensure that the arterial pressure is maintained at a suitable level These are (1) the depressor reflex and (2) the carotid sinus reflex

In the former a rise of pressure in the arch of the aorta stimulates nerve fibers ascending in the vagus trunk from the arch of the aorta to the hind brain Stimulation of these fibers slows up the heart and reduces blood pressure The slowing up of the heart is due to reflex augmentation of vagal tone and to reflex inhibition of sympathetic tone The fall in blood pressure is due to a generalized vasodilatation independent of the cardiac deceleration

If the carotid sinus is stimulated by external pressure or by an increased pressure of the blood within it or by stimulation of the sensory nerve to it there is again a reflex slowing up of the heart and a fall in blood pres ure Conversely, if the pressure of the blood in the sinus is reduced there

is an acceleration of the heart and a rise in blood pressure The reflex arc consists of the glossopharyngeal nerve (afferent), the cardio inhibitory and vasomotor centers, and the vagus and sympathetic nerves (efferent)

Reflex changes also occur in response to temperature changes The loss of heat from the body is regulated by the rate of blood flow through the skin and this, in turn, is controlled by sympathetic nerves A rise or fall in the temperature of the blood stimulates a central mechanism that produces cutaneous vasodilatation or vasoconstriction A secondary factor is the reflex cutaneous vasoconstriction which results from stimulation of cold receptors in the skin In man, the flow of blood through the muscles is not altered by environmental temperature unless shivering occurs

### Chemical Regulation of the Circulation

Epinephrine is released into the circulation from the adrenal medulla during fright asphyxia and muscular exercise and probably through the carotid sinus and depressor reflexes when the blood pressure falls It has a powerful effect on the circulation an effect closely resembling that of a generalized stimulation of the sympathetic nerves

In man small doses increase cardiac output, produce intense constriction of the arterioles capillaries and veins of the skin increase the rate of blood flow through voluntary muscles reduce the blood flow through the kidneys by constricting the efferent arterioles of the glomeruli and elevate the systolic blood pressure while the diastolic pressure remains stationary or falls Larger doses elevate both the systolic and diastolic blood pressures The effect is thus to divert blood from quiescent organs to active organs and to the brain and the heart

The cortex of the kidney contains an enzyme renin which upon intravenous injection produces a prolonged rise of arterial blood pressure This substance will be discussed in a section devoted to the humoral theory of hypertension

Finally it is important to remember that a given stimulus, whether chemical or nervous, produces different effects on the blood vessels supplying different tissues The various organs of the body have quite different roles in the body's economy, and the vessels supplying each organ are adjusted to the appropriate role

## THE NORMAL BLOOD PRESSURE

It is generally accepted that the upper limits of normal blood pressure regardless of age sex or other factors are 140 mm Hg for the systolic pressure and 90 mm Hg for the diastolic pressure Normal blood pressures for the population in general have never been classified according to age or sex The values generally cited are obtained either from insurance statistics or from statistics based on studies of relatively large groups of selected types of persons such as college students hospital out-patients and the inmates of institutions These values though probably representative are subject to selection and error in sampling

## ABNORMALITIES OF BLOOD PRESSURE

The blood pressure is lower during infancy and childhood than during adult life and in childhood does not differ between the sexes Between the ages of 20 and 40 the average systolic pressure is 120 mm Hg in the male and about 113 mm Hg in the female After the age of 40 there is a gradual increase in the systolic blood pressure to an average of approximately 136 mm Hg at the age of 60 Normally there is no concomitant rise in the diastolic pressure during this period nor does the systolic pressure rise above 140 mm Hg Average blood pressures for all ages are roughly 120-125 mm Hg systolic and 80 mm Hg diastolic

Since the blood pressure is a dynamic fluctuating physiological response it is constantly variable within certain limits Not only do environmental conditions modify the blood pressure at any given instant but so do conscious and subconscious nervous influences In the normal

person under controlled conditions both the systolic and the diastolic pressure may vary from 15 to 20 mm Hg over a 24 hour period Fluctuations in pressure are smallest in persons whose blood pressures under basal conditions are low in the normal range, the fluctuations are greater in persons with high normal pressures and are exaggerated in persons with even mild hypertension

When normal subjects are studied by means of the cold pressor test the rise in blood pressure is transient and rarely exceeds 15 mm Hg systolic and 10 mm Hg diastolic In persons with early hypertension and in some persons with normal resting pressures there is an exaggerated response to this test the rise in the blood pressure is two or three times greater than that ordinarily anticipated The rise and fall are so rapid however that the pressure returns to normal within a minute Three quarters of persons so responding have immediate ancestors who have had hypertension There is some evidence not yet conclusive that most of these patients will eventually develop classical hypertension

When hypertension becomes established, the response to the cold pressor test is frequently exaggerated often to as much as from 60 to 100 mm Hg

## HYPERTENSION
### (High Blood Pressure)

Hypertension may be defined as the more or less persistent elevation of the blood pressure above the accepted range for age sex and body weight There are two kinds of hypertension—the primary or idiopathic which is generally known as essential hypertension and the secondary or symptomatic which occurs as a manifestation of one or another of a variety of pathological states The distinction between the two is extremely important for the treatment of primary hypertension is entirely symptomatic whereas successful management of secondary hypertension is not infrequently possible through proper treatment of the predisposing disease From 85 to 95 per cent of all cases of hypertension are of the essential type

*Classification* —A simplified classification of the causes of hypertension appears in the accompanying table 46 I H Page has listed 47 known causes In some instances however the elevated blood pressure may be an associated condition rather than an etiologically related one

TABLE 46 —THE CLASSIFICATION OF HYPERTENSION (After Herndon)

1 Essential
   Benign
   Malignant
2 Nephritic
   Parenchymal
   Vascular
   Perinephritic
   Obstructive
3 Symptomatic
   Physiological
      Pain exertion emotion
   Cerebral
      Increased intracranial pressure
      Diencephalic stimulation
      Lesions in the brain stem
   Cardiovascular
      Aortic regurgitation
      Heart failure
      Arteriosclerosis
      Coarctation of the aorta
      Arteriovenous fistula
      Polycythemia
      Carotid sinus depression
   Endocrine
      Pituitary
         Basophilic adenoma
      Adrenal
         Hyperplasia
         Pheochromocytoma
         Cortical tumors

## ESSENTIAL HYPERTENSION
### (Arterial Hypertension Hyperpiesia)

Essential hypertension or hyperpiesia (Allbutt) has been defined by Ayman as an inherited disease in which the only demonstrable primary change is an elevation of blood pressure due to a functional generalized spasm of the arterioles with the cause of this constriction generally unknown Goldring and Chasis define it as a clinical entity in which an unknown pressor mechanism initiates vasoconstriction elevated blood pressure and vascular sequellæ The fundamental alteration is an increased resistance to the flow of blood in the systemic arteriolar bed consequently the essential

criterion for diagnosis is an abnormal elevation of the diastolic blood pressure. Ordinarily the systolic blood pressure is also elevated and the pulse pressure widened.

Essential hypertension is fundamentally a diagnosis by exclusion, exclusion of conditions commonly accompanied by the appearance of symptomatic hypertension—namely the inflammatory renal diseases, obstructive uropathies and certain cardiovascular, neurological and endocrine diseases. The secondary forms of hypertension are discussed later.

*Incidence.*—The incidence of essential hypertension is high. Among persons of college age, it is reported to occur in between 5 and 20 per cent. In general it occurs in about 7 or 8 per cent of the population. Some 25 per cent of all deaths of persons over 50 are due, directly or indirectly, to hypertension. This is a conservative estimate since renal, cardiac and cerebral deaths are often not attributed to the hypertension which is primarily to blame.

*Etiology.*—The cause of essential hypertension is unknown, but certain factors that contribute to the development of the condition are known.

*Heredity.*—In most cases there is an inherited predisposition to the development of hypertension. This has been noted by various authors and recent studies show that *cardiovascular disease is frequent among* the relatives of hypertensive patients, more particularly among immediate ancestors and siblings.

Hines and Brown studied this hereditary tendency to hypertension by means of the cold pressor test and concluded that the "abnormality of essential hypertension is a hereditary one which appears early in life and remains during life."

It seems evident that individuals whose blood pressures rise to abnormal levels under any circumstances are predisposed in varying degrees to the development of hypertension.

*Age.*—About 90 per cent of all cases of essential hypertension occur after the age of 40 years, from this age onward there is a steady increase in the incidence. Under the age of 30, glomerulonephritis is a far more common cause of elevated blood pressure and essential hypertension is uncommon.

*Sex.*—Despite conflicting statistics it appears that essential hypertension is somewhat more common among women than among men. This greater frequency of hypertension among women may be explained on the basis of previous occurrence of pyelonephritis or toxemia of pregnancy.

The toxemias occur more frequently among persons predisposed to hypertension and, in a high percentage of cases, the hypertension developed or aggravated during pregnancy persists permanently.

*Race.*—Essential hypertension is rare among certain Oriental races and native African Negroes. The children of Negroes who have intermarried with whites, however, are unusually subject to hypertension. Hypertension appears also to be more common among Jews than among Gentiles.

*Infections.*—There is no convincing evidence to show that focal infection contributes to the development of hypertension. Streptococcal infections, including scarlet fever, may lead to acute glomerulonephritis which, in turn, leads to hypertension. This, however, is not essential hypertension.

*Diet.*—Essential hypertension has been related by some observers to excessive protein in the diet. The Eskimos, however, an almost completely carnivorous race, show *no tendency to either hypertension or* cardiovascular renal disease.

*Psychosomatic factors* and *nervous* influences play an important role in the development and course of essential hypertension: (1) the changes that occur in the blood pressures of essential hypertension patients during periods of emotional stress are excessive; (2) during such episodes there is usually other evidence of profound sympathetic nervous stimulation including generalized arteriolar constriction, presumably mediated through the vasomotor center and the sympathetic nerves; (3) that this mechanism bears a causal relation to hypertension is suggested also by the effect of sympathectomy on hypertension, the basal blood pressure and the pressor response to emotional influences being generally reduced after the operation; and (4) success frequently results from the treatment of essen-

tial hypertension with sedatives through emotional and physical rest, and by suggestion

Essential hypertension is manifested first in many patients by exaggerated fluctuations in the blood pressure, fluctuations that can be related in degree as well as in time to the emotional status of the patient The personality and the emotional make-up of the hypertensive patient is of a special type which has existed since childhood, long before the appearance of hypertension Such vague symptoms as headache and nervousness also exist long before the appearance of sustained hypertension

Emotional upsets produce constantly recurring constriction of the arterioles as a result of sympathetic action There is a gradual hypertrophy of the smooth muscle in the arterioles and a gradual but progressive rise in the resting blood pressure The blood pressure finally remains elevated during periods of emotional tranquility and reacts to emotional outbursts in an even more exaggerated manner

The emotional lives of hypertensives correlate often with the onset and early course of their hypertension Faulty adaptation to the difficulties of life lead to emotional disturbances manifested by symptoms whose nature degree and extent depend on the intensity, and duration of the trauma and the susceptibility of the individual Psychoneurotic symptoms are (1) often multiple widespread and do not conform to any clinical entity (2) there are usually associated symptoms and signs of emotional instability such as irritability inability to concentrate excitability and attacks of weeping (3) physical examination is either negative or insufficient to explain the symptoms (4) there is a close relation between periods of stress and appearance of symptoms Clinical observation and the success of psychotherapy confirm diagnosis

The following evidence indicates that hypertensive patients fulfill these criteria (1) Most patients with early hypertension give history of emotional conflict dating back into infancy or early childhood (2) Personality studies show marked emotional responses to ordinary incidents of life (3) New symptoms often follow closely flare ups of old problems or appearance of new problems (4) Many patients exhibit a history of psychosomatic imbalance and of high blood pressure in their families (5) Early symptoms are often relieved by removal of environmental difficulties sedation and suggestion The fundamental mechanism is thus unexplained but may be an endocrine imbalance in which there is an altered pattern of reaction to stress

*Other Factors* — Toxic factors have been suggested as a cause of hypertension but the evidence is not convincing Glandular disturbances have also been suggested as a cause, and these do of course play a primary role in certain types of secondary hypertension But there is no evidence to show that they are important in essential hypertension The use of tobacco has not been shown to have any etiological relationship to hypertension

## Humoral Mechanism of Renal Origin

The experimental work of Goldblatt I H Page and others has emphasized and popularized the fact that persistent hypertension can be induced in various species by constriction of both main renal arteries or constriction of one main renal artery and extirpation of the contralateral kidney This type of experimental hypertension has suggested that elevation of the blood pressure in man may be due to renal vascular disease or any other kind of renal disease that has similar effects on the renal circulation The essential change in renal hemodynamics accompanying hypertension is a reduction in renal blood flow but with a maintenance of glomerular filtration This means that the systemic blood pressure must be increased The interference with renal blood flow must be distal to the glomeruli in the glomerular efferent arteries the changes in the afferent arteries are secondary

Hypertension which follows constriction of the main renal arteries must be humoral in nature and renal in origin Renal denervation and all types of sympathetic nervous interruption fail to prevent or abolish this type of hypertension Transplantation of the kidneys to the other parts

of the body with complete section of all nervous connections does not abolish the hypertensive response. Obstruction to the renal veins at the time of renal arterial constriction does prevent the appearance of hypertension. Finally, blood from a kidney whose main renal artery is constricted is itself vasoconstrictor and pressor.

The renal pressor substance is renin, a proteolytic enzyme elaborated by the kidney. When renin is injected intravenously into the experimental animal, a rise in blood pressure follows promptly, and this effect is not abolished by the removal of any or all of the viscera excepting by bilateral adrenalectomy, following which there is a progressive decline in the pressor response to the injection of the renin.

Renin itself is not pressor, but it reacts in the blood stream with a heat labile, nondialyzable pseudoglobulin preangiotonin (hypertensinogen, renin activator or hypertensin precursor) to form angiotonin (hypertensin). Preangiotonin is apparently formed in the liver. The amount of this substance circulating in the blood is increased in experimental renal hypertension and in human essential hypertension.

Angiotonin is thermostable and dialyzable. Its physiological effects are similar to those produced by the injection of renin intravenously in experimental animals. Angiotonin circulating in the blood stream produces arteriolar constriction sufficient to raise the peripheral resistance. The blood flow is maintained however by the augmentation of the cardiac work.

There is a mechanism that interferes with this phenomenon. Normal serum contains an enzyme, hypertensinase, which is found in large amounts in the renal cortex and in the intestinal mucosa and in moderate amounts in the pancreas, the spleen and the liver. Hypertensinase may suppress the effects of hypertensin. Hypertensinase disappears almost completely from the circulation of dogs who have undergone nephrectomy.

The humoral theory of hypertension may be outlined briefly as follows. Decreased renal blood flow, presumably due to arteriolarsclerosis, reduces the pulse volume in the renal parenchyma. The vascular changes produce renal cellular damage particularly in the tubules and renin is released into the blood stream. Renin interacts with preangiotonin to form angiotonin, which produces a generalized arteriolar constriction sufficient to raise the peripheral resistance. The blood flow is maintained by increased cardiac effort. The effect on the various systemic arteries in the body varies according to the particular qualities of each system. In the kidneys there is further impairment of the hemodynamics and a vicious cycle is compounded since more renin is produced. Hypertensinase may act as a physiological counter measure.

HUMORAL MECHANISM OF RENAL ORIGIN AS A CAUSE FOR HYPERTENSION

| RENIN | + PREANGIOTONIN → | ANGIOTONIN |
|---|---|---|
| (Renal Pressor Substance) | (Renin Activator Hypertensin Precursor) | (Hypertensin) |
| (A proteolytic enzyme of renal origin not directly pressor) | (A plasma globulin of hepatic origin) | (The active pressor agent) |

MECHANISM FOR COMBATTING THE HUMORAL CAUSE FOR HYPERTENSION

| ANGIOTONIN | + HYPERTENSINASE → | Inactive substance |
|---|---|---|
| (Hypertensin) | (Angiotonase) (An enzyme of renal and perhaps other origins) | |

(After John F. Fulton, Textbook of Physiology, p. 906, W. B. Saunders & Co.)

One of the more important controversies about the humoral theory is concerned with the rôle of renal disease and renal ischemia in the production of hypertension. It is well known that not all cases of hypertension are accompanied by arterial and arteriolar sclerosis, nor are all instances of vascular sclerosis accompanied by hypertension. Essential hypertension has been observed repeatedly in man when there has been no evidence of renal ischemia or of preexisting altered renal physiology. This may indicate no more than that renal dysfunction precedes renal pathology. Many observers feel that the primary renal origin of essential hypertension is not proved and that the observed renal ischemia is a sequel to and not a cause of essential hypertension.

Recently Shorr, Zweifach and their associates have reported the regular participation in both experimental renal and human essential hypertension of two hitherto undescribed humoral vasoactive principles which they have termed VEM* and VDM.** VEM is of renal and VDM of hepatic origin, both factors appearing normally

* VEM—Vaso-Excitor material. Chemically called Ferritin.
** VDM—Vaso-Depressor material.

only under anaerobic conditions. Their vascular effects are exerted on the muscular vessels—the metarterioles and precapillary sphincters—of the terminal vascular bed. VEM potentiates the response of these vessels to topically applied epinephrine and enhances their spontaneous constriction and dilatation. VDM exerts exactly opposite effects on the same capillary vessel. On the basis of these vascular actions, the workers suggest that VEM and VDM constitute a homeostatic system contributing to the regulation of peripheral vascular behavior.

In the normal state, neither factor is detectable in blood. According to the findings of these workers in experimental renal hypertension, VEM appears in high concentrations in the blood stream during the acute stage. This results from a renal metabolic defect as a consequence of which VEM formation is no longer confined to the anaerobic state but takes place in oxygen as well. When the blood pressure stabilizes itself at the chronic hypertension level, the humoral VEM is accompanied by physiologically equivalent amounts of VDM continuously released by the aerobic liver. This aerobic formation of VDM by the liver is presumed to be a homeostatic response to sustained high concentrations of VEM in the blood stream.

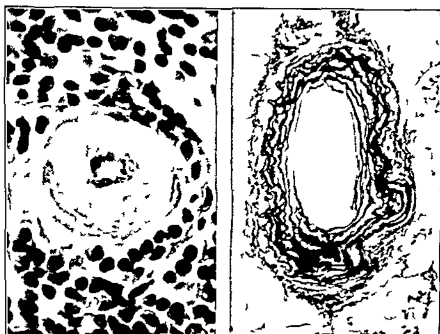
Schorr, Zweifach and their associates have demonstrated the appearance of both VEM and VDM in the circulation during the hypertensive syndrome and their disappearance when the blood pressure returns to normotensive levels after removal of the renal artery clamps.

They have found that both principles are also regularly present in chronic human essential hypertension in approximately the same amounts as in experimental renal hypertension. The renal origin of VEM and the hepatic origin of VDM in man has been established by bioassays of blood obtained by catheterization of the renal and hepatic veins. VEM and VDM are also present in the blood during the hypertension of Cushing's syndrome and the hypertension of toxemia of pregnancy. In the latter case they disappear on resumption of normotensive levels after delivery.

The exact role of these vasoactive principles in the evolution of the hemodynamics of the hypertensive state still awaits clarification. Unlike hypertensin, which, through its action on the arterioles, exerts acute effects on blood pressure, these principles would be expected to exert chronic effects, effects exerted initially on the capillary muscular vessels and secondarily on the arterioles (which are more directly responsible for increases in peripheral resistance).

## Pathology

The pathological changes of hypertension consist of those changes in the cardiovascular system which occur in response to overwork or strain. Their extent depends upon both the degree of strain and its duration. They are essentially the same in all types of hypertension, although the details may vary in accordance with associated or complicating disease processes. In the early stages of essential hypertension there are no demonstrable structural changes, thus indicating that the primary etiological disturbance is functional.



*The Arteries.*—The primary lesion in hypertension is a diffuse hyperplastic arteriolar sclerosis, a hypertrophy of the intima, the internal elastic lamina, and the media. The intima shows hyperplasia and a hyaline thickening of the subendothelial layer. The internal elastic lamina shows a dramatic multiplication and reduplication. The media shows a thickening and hypertrophy of the muscle fibers and a proliferation of the connective tissue. These changes, particularly those in the intima, narrow and at times obliterate the lumen of the vessel. Subsequently degenerative changes, chiefly fibrosis and the deposition of fat, occur. The adventitia is not involved.

These vascular changes are usually diffuse but not generalized. They are almost always more frequent and more pronounced in the kidneys than in other organs. They represent a hyaline degeneration of the vessel wall and are the usual picture of the arterioles in benign hypertension.

As the process advances and the blood pressure rises, there is an accelerated stage in which increased cellular proliferation occurs within the intima.

The new cells are loosely connected by delicate collagen fibrils and are arranged in concentric layers, often piling up so that they encroach upon the lumen, which is partially or completely occluded.

The final or malignant phase of hypertension is characterized by the appearance of necrotizing lesions. The vessel walls lose their outlines as fibrinoid changes occur and focal areas of necrosis appear in the intima. These changes are accompanied by cellular degeneration, diffusion of blood, and the infiltration of polymorphonuclear and mononuclear cells, fibroblasts and pigment laden macrophages. The end result is partial or complete occlusive thrombosis.

FIGS 166–167 —Arterial changes in hypertension (Boyd s Textbook of Pathology )
FIG 166 —Hyaline degeneration × 510 FIG 167 —Elastic hyperplasia × 500

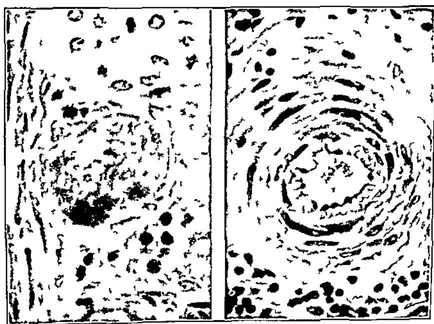


FIG 168 —Arteriolar necrosis × 430 FIG 169 —Cellular hyperplasia × 340

Hypertension is essential to the development of such lesions but not to the development of atherosclerotic changes in the aorta and other great vessels or for the calcareous changes in many of the medium sized arteries Such changes characteristic of arteriosclerosis frequently accompany hypertension, but they do not always do so and are not an integral part of the pathology of hypertension

emia secondary to an inadequate blood supply to the hypertrophied myocardium

*The Kidneys* — The essential lesion in the kidney is a thickening and narrowing of both the efferent and the afferent arterioles and the characteristic subintimal deposition of hyaline in these vessels This is the earliest lesion found in patients with hypertension These vascular changes lead to an obliteration and fibrosis of the glomeruli and

TABLE 47 —THE GROUPING OR GRADING OF ESSENTIAL HYPERTENSION
(After Wagener and Keith)

| | *Group I* *Early or Mild Benign* | *Group II* *Moderate Benign* | *Group III* *Late or Severe Benign* | *Group IV* *Malignant Syndrome* |
|---|---|---|---|---|
| *Age* | 30 to 6[illegible] | 21 to 59 | 2[illegible] to 5[illegible] | 8 to 64 |
| Symptoms | None to slight Health good | Slight Early morning headaches vertigo General health good | Definite Headache nervousness vertigo tiredness dyspnea nocturia | Severe Headaches disturbed vision muscle pains weakness dyspnea |
| Blood pressure | Systolic 150 to 200 Diastolic 100 to 1[illegible]0 Occasionally normal at rest | Systolic 200 to 2[illegible]0 Diastolic 100 to 130 Lower at rest but never normal | High Almost always over 1[illegible]0 systolic and 110 diastolic | High and fixed Systolic usually over [illegible]50 diastolic seldom below 140 |
| Retinal Changes | None or minimal arterial narrowing | Definite arteriolar sclerosis Arteriovenous compression No retinitis | As before plus retinitis with edema white spots cotton wool patches and hemorrhages | As in group 3 plus papilledema |
| Heart | Slight or no demonstrable change | Slight enlargement Left ventricular preponderance Good function | Enlarged Definitely diminished reserve | Enlarged Actual or impending failure |
| Urine | Normal | Mild albuminuria and casts | Albumin casts and often red cells | Albumin casts and red cells |
| Renal Function | Normal | Slightly decreased Urea clearance 30 to 40 cc | Decreased Urea clearance 20 to 30 cc | Function usually low with urea clearance [illegible] to [illegible]0 cc |
| Brain | Normal | Normal | Cerebral disturbances or accidents frequent | Disturbances present |
| Five Year Mortality | 30 per cent | 4[illegible] per cent | 80 per cent | 99 per cent |

*The Heart* —Initially the heart shows concentric hypertrophy with left ventricular preponderance due to enlargement of the individual muscle fibers in the wall of the left ventricle Persistent cardiac strain results eventually in dilatation As the left side of the heart fails, increased pressure in the pulmonary circulation increases the load on the right ventricle, which then undergoes similar changes

Hypertrophied hearts show some evidence of muscle damage fibrosis atrophy and the deposition of lipoid material but these changes are attributed to an associated nutritional deficiency most probably anox-

subsequently to atrophy of the involved tubules The end result is a true granular primary contracted kidney since the condition is primarily vascular and not renal

There is eventually a tremendous increase of connective tissue in the kidneys replacing the destroyed parenchyma and arising in part from nutritional changes due to the impaired circulation The process is characteristically patchy so that areas of essentially normal or hypertrophied renal tissue may be seen amidst areas of advanced atrophy and fibrosis It is this alternation which accounts for the grossly granular surface and irregular cortex

The urine from these kidneys contain a little protein and a few casts. When many of the glomeruli have been destroyed, the kidneys lose their ability to concentrate urine. Renal function tests show that in the terminal stages all renal functions are depressed and there is an increase in proteinuria.

Malignant hypertension tends to terminate in uremia. In these cases, there is a marked hyaline and collagenous thickening of the intima of the arterioles, areas of intimal necrosis, and thrombotic occlusion of many afferent glomerular arteries, a picture of necrotizing renal arteriolitis. The urine of these patients contains large quantities of albumin and large numbers of casts and erythrocytes. Hematuria is a prominent feature and is often sufficient to suggest actual hemorrhage. It is to be emphasized however that the kidneys of those patients who do not die of uremia do not show more than the usual changes of hypertension.

## Clinical

The general or systemic manifestations of hypertension are those of chronic fatigue—both nervous and physical. Mentally, there is irritability, depression, fatigability, loss of concentration, worry and insomnia. Headache is a common complaint at all stages of the disease and under a variety of circumstances. It is probably of diverse origins as is discussed in the section on cerebral symptoms. That many symptoms arise on a vasomotor basis is evident in many instances where there are visible stigmata of vasomotor instability. Local symptoms arise most frequently from cerebral, cardiac or renal involvement.

*Cardiac.*—The clinical evolution of the heart in hypertension is characteristic. Hypertension, especially if benign, may exist for a long period of time without the development of cardiac enlargement. Then the heart begins to enlarge at first to the left, later toward the right as well. To a certain point no murmurs appear but the apical beat becomes forceful and the aortic second sound is accentuated and ringing. During the progressive enlargement of the heart, as the valve rings stretch and the heart chambers dilate, murmurs appear. Characteristically a systolic murmur appears at the apex, later an aortic systolic or diastolic murmur may occur along the left sternal border. Disturbances in rhythm are apt to appear, usually extrasystoles, auricular fibrillation or, less commonly, flutter. Since the essential strain is on the left ventricle, the chief symptom is ordinarily dyspnea, followed by the classical stages of left heart failure, paroxysmal dyspnea, cardiac asthma and pulmonary edema. Right heart failure occurs eventually and with it the appearance of generalized edema. There is often a complaint of a dull precordial ache. True angina pectoris is ordinarily due to the complicating coronary sclerosis which occurs clinically in at least half the patients with hypertension.

## Cerebral Symptoms

The cerebral symptoms which accompany hypertension may be discussed conveniently in four general groups.

1) *Functional Symptoms.*—These symptoms include throbbing sensations, vertigo, headaches, mental fatigue, failure of concentration, irritability and the like which may occur before there is evidence elsewhere of vasospastic or organic vascular changes. There may be impairment of memory. Headaches are commonly occipital in location and usually appear in the mornings. Preexisting migraine is aggravated. Many of these symptoms are common to any condition of ill health.

2) *Vascular Symptoms.*—These symptoms are due to structural alterations in the cerebral vessels and to hemorrhage or thrombosis. They occur largely in older patients in whom arteriosclerotic changes have usually occurred in the vessels. Cerebrovascular accidents (*e.g.* spasm, hemorrhage or thrombosis) may produce syndromes ranging from slight transient episodes of numbness and tingling in the extremities, mental confusion and aphasia to hemiplegia and death. Milder attacks tend to clear without residual effects; even a patient with hemiplegia may recover completely. Following severe attacks, mental changes

(impaired memory, loss of concentration irritability, *etc*) usually persist

The role of cerebral vascular spasm in these cases is not entirely clear. It may be deduced from the fact that there is retinal arterial spasm in many instances. It is suggested also by the transitory and varying nature of the focal cerebral symptoms. It is probably but one manifestation of a generalized vasoconstriction which manifests itself at such times by an increased blood pressure. Pathologically there is support for this theory in the appearance of the brain which is pale, relatively bloodless and edematous.

3) *Uremic Symptoms*.—These symptoms appear in those cases in which progressive renal failure is the dominant complication. There is a progressive general depression and apathy which leads from drowsiness into stupor. The patient can be aroused only with difficulty and is disoriented and delirious. Finally coma supervenes with deep (Kussmaul) breathing and terminally stertorous breathing which may be punctuated by periods of apnea. Tremors, twitchings and clonic convulsions are common terminally.

4) *Hypertensive Encephalopathy*.—These cerebral changes occur most frequently when there has been a rapid rise in the blood pressure above its previous high levels. They are usually associated with papilledema. The clinical manifestations are those of focal or diffuse cerebral disturbances. Commonly there are severe headache, nausea and vomiting, convulsions and apathy, somnolence or coma. Less frequently paresthesias, amaurosis, aphasia and hemiplegia occur. These symptoms and signs may occur individually or in any combination. The attacks are often sudden and dramatic and epileptiform in character like those seen in eclampsia. Other attacks may be protracted for weeks or months so that the clinical picture resembles that of brain tumor. The focal phenomena such as amaurosis, aphasia and paralyses are characteristically transitory. Neurological findings usually include exaggerated tendon reflexes, often positive Babinski signs, and occasional signs of meningeal irritation (stiffness of the neck and legs).

## OPHTHALMOSCOPIC FINDINGS

Ophthalmoscopy is an invaluable aid in the diagnosis and study of cardiovascular and renal disease. In no vascular condition is this more true than in hypertension, since the arterioles throughout the body are the chief point of attack and these can be visualized readily and directly only in the retina.

The vascular changes in the retina in hypertension may be described in several stages.

1) *Pre-organic Stage*.—The earliest change observed in the retinal vessels is that of increased arterial tone in which the lumen

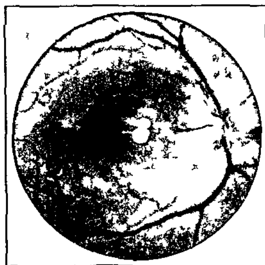

FIG 170.—Arteriospastic hypertensive narrowing of retinal arterioles. (Courtesy of Department of Ophthalmology, Temple University School of Medicine.)

of the arterioles is uniformly narrowed. The constrictions may be localized and are either transitory or variable.

2) *Earliest Organic Changes*.—The first recognizable change in the arterioles is a hypertrophy of the tunica media. This produces a narrowing of the lumen and gives it an irregular appearance. The reflection of light from the wall of the arteriole is increased and produces a coppery or steely appearance. Where the arterioles and veins are in contact, the increased thickness of the arteriolar wall and the increased arteriolar

pressure produce indentations in the readily compressible veins (arteriovenous nicking)

3) *Retinal Arteriosclerosis* —The arterioles are small and narrow and irregularly indented There is an exaggerated light reflex The vascular wall is brightly visible The veins are full and tortuous and are compressed where they are crossed by an artery This compression is at first a nick in the vein, but, later the vein is not visible for a short distance on either side of the point of crossing Finally, when the constriction is almost complete an S shaped twist appears in the vein Where the vein crosses an artery, this curve is distinctly U shaped At this stage there are frequently punctate hemorrhages and white punctate spots of hyaline or fatty degeneration arranged in a radiating manner about the macula The discs are normal or slightly congested, but there is no papilledema

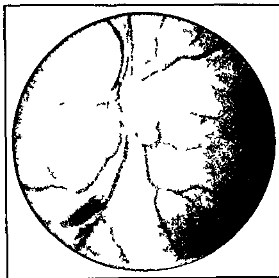

Fig 171 —Mixed sclerotic and spastic hypertensive focal constrictions with retinopathy of hypertension (Courtesy of Department of Ophthalmology Temple University School of Medicine)

Fig 172 —Retinopathy of malignant hypertension (Courtesy of Department of Ophthalmology Temple University School of Medicine)

4) *Hypertensive Neuroretinitis* (*Vasospastic or Albuminuric Retinitis*) The characteristic findings in hypertensive retinitis are cotton wool patches edema of the nerve fibers distal to the points of arteriolar narrowing occlusion, or spasm The arterioles are small and almost bloodless There is dilatation and stasis of the capillary bed resulting in serous and hemorrhagic transudations into the retina Flame shaped hemorrhages are usually present This stage of retinitis may be superimposed upon any preceding stage of organic change and a similar picture occurs in the terminal stages of glomerulonephritis It may also follow a pure vasospastic retinitis in which there is an absence of organic changes in the arterioles as in toxemia of pregnancy or in acute arterial hypertension and in these the changes may regress to the point of normality

5) *Papilledema* —The final stage is the development of papilledema which indicates the presence of increased intracranial pressure resulting from cerebral edema The discs may attain a height of 4 diopters or more

## Laboratory Findings

1) *X ray of the Heart* —The existence of minimal degrees of cardiac hypertrophy in the early stages of hypertension cannot always be determined roentgenologically but a preliminary film is of value in ascertaining whether or not the cardiac shadow is widened for purposes of comparison with later films Periodic roentgen examinations will then disclose the rate of cardiac enlargement

2) *X rays of the Kidneys* —Roentgen examination of the kidneys, utilizing intra

venous urography, may reveal abnormalities of the urinary tract in patients with hypertension, but it is seldom that the abnormalities prove to have any relation to the hypertension If the examination of the urine and renal function studies are normal roentgen examination of the kidneys should be done only on the basis of some other indication If these studies are abnormal indicating a possible renal origin for the hypertension urography is advisable

3) *Electrocardiogram* —The electrocardiogram may give the first evidence of an organic change in the heart in response to hypertension Changes characteristic of left ventricular strain appear commonly in the electrocardiogram before there is any apparent enlargement of the heart by roentgen examination

The earliest electrocardiographic picture is that of left axis deviation The characteristic electrocardiographic pattern of hypertrophy is that of so-called left ventricular strain in which there is increased voltage in the R waves depression of the RS-T segment of 0 5 mm or more in lead I and flattening inversion or other definite abnormality of the T wave in lead I Such changes occur in the left arm lead in horizontally placed hearts and in the left leg lead in vertical hearts Slurring of the Q R-S complex occurs subsequently and this may in turn lead to various types of conduction defects

The failure of the coronary circulation to compensate for the increased mass of myocardium to be supplied with oxygenated blood in cardiac hypertrophy and the frequent association of coronary artery disease in the presence of hypertension results in myocardial damage and those electrocardiographic changes characteristic of coronary artery disease

One important use of the electrocardiogram as with the roentgen examination of the heart is to assess the speed and degree to which the heart suffers damage Serial electrocardiograms over long periods of time are of great value in determining the course of the disease as it is reflected on the functional capacity of the myocardium

4) *Renal Function Tests* —The most practical and useful test for renal function is the concentration test by which the power of the renal tissue to concentrate urine is determined The principle of this test is to restrict the fluid intake, but not the ingestion of food for a period of time which permits the kidneys to concentrate the urine to its maximum capacity Special modifications of the test have been described by Volhardt Mosenthal Fishberg and Ayman

Formed elements may not appear in the urine of patients with hypertension until there has been renal impairment of a considerable degree and for a prolonged period of time except in malignant hypertension when urinary abnormalities may appear promptly and dramatically The concentration test may be supplemented when indicated by other tests of renal function the blood urea or N P N the phenosulfophthalein test urea clearance diodrast excretion inulin clearance creatinine clearance *etc*

5) *Blood Counts* —Whether anemia or polycythemia exists should be determined by means of a complete blood count in each patient with hypertension

6) *Basal Metabolic Rate* —The basal metabolic rate should be determined in all patients with hypertension who are suspected of having hypo- or hyperthyroidism

7) *Blood Chemistry* —The blood urea or the N P N should be determined in all instances where renal function is suspected of being impaired A fasting blood sugar or a glucose tolerance test should be performed on all patients suspected of having diabetes mellitus The blood-cholesterol level should be studied in patients with significant arteriosclerosis or in those in whom an abnormality of fat metabolism might be present

The circulation time of the blood is normal in cases of hypertension until congestive heart failure supervenes The blood volume and the acid base balance are normal in uncomplicated hypertension The blood proteins are not reduced by hypertension *per se*

## Differential Diagnosis

Hypertension may be produced by or accompany a variety of pathological conditions Essential hypertension affects by

far the greatest number of persons For purposes of discussion, hypertension may be divided into three general groups

1) *Essential Hypertension* — This diagnosis may be made when the patient has abnormally high systolic and diastolic blood pressures in the absence of any renal or other disease which is known to result in an elevated blood pressure It is essentially a diagnosis by exclusion

2) *Renal Hypertension* —(a) *Glomerulonephritis* —The blood pressure is ordinarily elevated during the acute stage of glomerulonephritis and this elevation is, in general in proportion to the degree of activity of the inflammatory process This elevation of blood pressure is essentially a symptomatic hypertension Following the acute stage of glomerulonephritis the blood pressure frequently falls to normal even though the persistence of urinary findings indicates that the renal lesion is still active

During the chronic stage of glomerulonephritis the blood pressure is most commonly normal despite the progression of the renal lesion With the development of the late stage of glomerulonephritis, the blood pressure becomes elevated in about 75 per cent of the cases Its presence indicates that the nephritic process has been complicated by diffuse arteriolar disease within the kidney and this arteriolar process becomes the dominant feature in the progression of the case

Patients with late glomerulonephritis are often indistinguishable from patients with late essential hypertension except that they may give a history of antecedent acute or chronic nephritis The pathological pictures are indistinguishable so that it is impossible to tell on this basis whether the inflammatory or vascular lesions were primary In general patients with glomerulonephritis exhibit greater proteinuria earlier and more pronounced renal failure lower blood pressure and less advanced degrees of cardiac involvement than do patients with essential hypertension who develop renal damage

b) *Toxemia of Pregnancy* —In toxemia of pregnancy (preeclampsia unless convulsions or coma occur) the most constant and characteristic lesion is a diffuse degenerative renal lesion The disease is an acute vascular syndrome, occurring during the latter half of pregnancy and closely resembling glomerulonephritis in producing hypertension, albuminuria, and edema Toxemia of pregnancy occurs in from 5 to 10 per cent of pregnant women whose blood pressures have been normal previously It occurs in over 50 per cent of women whose blood pressures have been elevated previously Permanent hypertension persists in about 25 per cent of the cases and differs in no essential clinically or pathologically from other types of chronic hypertensive disease

c) *Pyelonephritis* —Chronic pyelonephritis with contracted and scarred kidneys is commonly accompanied by hypertension and ultimately renal failure In the late stages these patients cannot be distinguished from those with essential hypertension except on the basis of an adequate history The primary lesion is of course renal and the hypertension is secondary Among the surgical conditions associated with hypertension unilateral atrophic pyelonephritis has been followed by the greatest percentage of permanent reductions in blood pressure when nephrectomy has been performed

d) *Disseminated Arteritides* — Hypertension is present in the disseminated arterial diseases such as lupus erythematosis periarteritis nodosa *etc* only when there is extensive involvement of the renal arteries This suggests of course that the hypertension in these cases is of renal vascular origin

e) *Congenital Polycystic Kidneys* —This congenital lesion is an uncommon cause for hypertension but must be considered in all instances where there is evidence of renal disease Suspicion aroused by the urinary findings and often by the discovery of a palpable mass in the abdomen can be confirmed readily by pyelography

f) *Surgical Renal Disease* —In the instances of hypertension accompanying hydronephrosis urinary lithiasis renal tuberculosis chronic perinephritis and renal tumors (especially Wilm s tumor) the hypertension appears to be related to the extent of the parenchymal damage and to the degree of renal vascular sclerosis rather than to the primary disease Increased back pressure does not produce hypertension unless it is

bilateral and acute. In the presence of a surgical renal lesion it is important to determine whether the hypertension is secondary to the renal pathology, or whether it is an *unrelated coexisting essential hypertension.*

*g) Renal Atherosclerosis.*—The progressive narrowing of the renal arteries by atherosclerosis is frequently associated with hypertension. The experimental studies of Goldblatt and others suggests that there may be an etiological relationship between this *renal arterial narrowing and hypertension.* It is however usually impossible to determine whether the hypertension preceded the atherosclerotic process, or vice versa.

*h) Aneurysm of the Renal Artery.*—We have seen a case of marked hypertension which was relieved completely by removal *of a left kidney and aneurysmal renal artery.* Pathological study of the kidney failed to reveal any changes whatsoever.

3) *Symptomatic Hypertension.*—(*a*) *Physiological Hypertension.* The normal response of the organism to the stimuli of pain, excitement, emotion and exertion is a generalized *vasoconstriction and an increase in the* heart rate producing a transient elevation of the blood pressure. The exaggerated response of many young individuals has suggested that an excessive and oft repeated response of this nature may be a precursor for a sustained and permanent essential hypertension.

*b) Cerebral Hypertension.*—Increased intracranial pressure is commonly accompanied by an increase in the systemic blood pressure. The hypertension which accompanies organic lesions of the diencephalon and the brain stem is probably due to direct stimulation of the vasomotor centers.

*c) Cardiovascular Hypertension.*—Hypertension of a compensatory character may accompany instances of *aortic regurgitation and of polycythemia.* The hypertension which exists in the upper extremities in *coarctation of the aorta* is a physiological attempt to compensate for the diminished blood flow below the obstruction and particularly to the diminished renal blood flow. The hypertension in *arteriovenous fistula* is also *a compensatory mechanism* in response to the shunting of blood from the arterial to venous circulations. In arteriovenous fistula there is an increase in both the cardiac output and the circulating blood volume. The work of the heart is increased so that hypertrophy ordinarily *follows eventually.* Hypertension arising in instances of *advanced arteriosclerosis* is apparently a mechanism which attempts to compensate for the loss of elasticity of the walls of the major vessels. In these cases the systolic blood pressure is elevated and the diastolic blood pressure remains normal *or relatively so. Since the work of the heart* is not significantly increased, cardiac hypertrophy is not a prominent feature.

*d) Endocrine Hypertension. Basophilic adenomas of the pituitary gland* are almost always accompanied by hypertension. *Pheochromocytomas* (paragangliomas) arising *from the adrenal medulla or from the* chromaffin bodies in the paravertebral region may produce *either paroxysmal or sustained* hypertension due to the secretion of excessive amounts of adrenalin into the circulation. Two tests are of considerable value in establishing the presence of such a *tumor: the histamine test and the benzodioxane test.* (For discussion of these tests see Chapter 16.)

*Adrenal cortical tumors* (adenomas, carcinomas) produce hypertension in association with other manifestations of an excessive secretion of adrenocortical hormones. *There is no excessive secretion of adrenalin.* Such tumors produce precocious puberty in children and Cushing's syndrome in adults. In *hyperthyroidism* there is systolic but not diastolic hypertension. The elevated blood pressure is a result of an increase in the force and rate of the heart beat. The blood pressure is not related to the degree of hyperthyroidism and it is not necessarily relieved by thyroidectomy. Hypertension appearing at the time of the *menopause* may be influenced by the suppression of the ovarian secretions but it is not primarily endocrine in origin.

## TREATMENT

The treatment of essential hypertension may *be discussed most conveniently in three* phases—the treatment of symptoms, efforts to reduce the elevated blood pressure, and

far the greatest number of persons. For purposes of discussion, hypertension may be divided into three general groups.

1) *Essential Hypertension.*—This diagnosis may be made when the patient has abnormally high systolic and diastolic blood pressures in the absence of any renal or other disease which is known to result in an elevated blood pressure. It is essentially a diagnosis by exclusion.

2) *Renal Hypertension.*—(a) *Glomerulonephritis.*—The blood pressure is ordinarily elevated during the acute stage of glomerulonephritis and this elevation is in general in proportion to the degree of activity of the inflammatory process. This elevation of blood pressure is essentially a symptomatic hypertension. Following the acute stage of glomerulonephritis, the blood pressure frequently falls to normal even though the persistence of urinary findings indicates that the renal lesion is still active.

During the chronic stage of glomerulonephritis the blood pressure is most commonly normal despite the progression of the renal lesion. With the development of the late stage of glomerulonephritis, the blood pressure becomes elevated in about 75 per cent of the cases. Its presence indicates that the nephritic process has been complicated by diffuse arteriolar disease within the kidney, and this arteriolar process becomes the dominant feature in the progression of the case.

Patients with late glomerulonephritis are often indistinguishable from patients with late essential hypertension except that they may give a history of antecedent acute or chronic nephritis. The pathological pictures are indistinguishable so that it is impossible to tell, on this basis, whether the inflammatory or vascular lesions were primary. In general, patients with glomerulonephritis exhibit greater proteinuria, earlier and more pronounced renal failure, lower blood pressure and less advanced degrees of cardiac involvement than do patients with essential hypertension who develop renal damage.

b) *Toxemia of Pregnancy.*—In toxemia of pregnancy (preeclampsia, unless convulsions or coma occur) the most constant and characteristic lesion is a diffuse degenerative renal lesion. The disease is an acute vascular syndrome, occurring during the latter half of pregnancy and closely resembling glomerulonephritis in producing hypertension, albuminuria and edema. Toxemia of pregnancy occurs in from 5 to 10 per cent of pregnant women whose blood pressures have been normal previously. It occurs in over 50 per cent of women whose blood pressures have been elevated previously. Permanent hypertension persists in about 25 per cent of the cases and differs in no essential clinical or pathologically from other types of chronic hypertensive disease.

c) *Pyelonephritis.*—Chronic pyelonephritis with contracted and scarred kidneys is commonly accompanied by hypertension and ultimately renal failure. In the late stages these patients cannot be distinguished from those with essential hypertension except on the basis of an adequate history. The primary lesion is of course renal and the hypertension is secondary. Among the surgical conditions associated with hypertension unilateral atrophic pyelonephritis has been followed by the greatest percentage of permanent reductions in blood pressure when nephrectomy has been performed.

d) *Disseminated Arteritides.*—Hypertension is present in the disseminated arterial diseases, such as lupus erythematosis, periarteritis nodosa, *etc.*, only when there is extensive involvement of the renal arteries. This suggests, of course, that the hypertension in these cases is of renal vascular origin.

e) *Congenital Polycystic Kidneys.*—This congenital lesion is an uncommon cause for hypertension but must be considered in all instances where there is evidence of renal disease. Suspicion aroused by the urinary findings and often by the discovery of a palpable mass in the abdomen can be confirmed readily by pyelography.

f) *Surgical Renal Disease.*—In the instances of hypertension accompanying hydronephrosis, urinary lithiasis, renal tuberculosis, chronic perinephritis, and renal tumors (especially Wilm's tumor), the hypertension appears to be related to the extent of the parenchymal damage and to the degree of renal vascular sclerosis rather than to the primary disease. Increased back pressure does not produce hypertension unless it i

*Reduction of Blood Pressure* —The desirability of reducing the blood pressure in essential hypertension is open to debate

Undoubtedly it is advisable when symptoms are relieved or ameliorated by its reduction In instances of asymptomatic essential hypertension it has yet to be conclusively proved how much is to be gained by reduction in blood pressure *per se* However it seems logical to lessen the strain on the entire vascular tree

There are three measures for which a brief may be held at present—the medical treatment using thiocyanate, the low sodium low protein diet and the surgical operation of sympathectomy

The potassium ammonium or sodium salts of thiocyanate may be administered to hypertensive patients who exhibit reasonably good renal function and who are not in heart failure These compounds should be used only when facilities exist for the periodic determination of the blood thiocyanate level

One cannot specify a given dosage for any one patient The maintenance doses must be regulated according to the blood thiocyanate level Generally an initial dose of 0 2 gm of potassium thiocyanate given three times a day in the form of enteric coated tablets or capsules for 3 days is followed by 0 2 gm twice a day for 4 days The blood thiocyanate level and the N P N are then determined If the blood thiocyanate level is 6 mg or less the dosage is continued at 0 2 gm twice a day for another week When the blood thiocyanate level exceeds 8 mg the dosage should be decreased to 0 2 gm and 0 4 gm as a total dose on alternate days if the blood level is between 8 and 10 mg or to 0 2 gm daily if the blood level is above 10 mg Within a few weeks it is possible to stabilize the majority of patients at a level of between 8 and 10 mg which is desirable

Determinations of the blood thiocyanate level may then be done at intervals of from 2 to 4 weeks If higher levels between 10 and 12 mg are desired determinations of the blood level should be done more frequently The individual response to thiocyanate varies widely among patients and in the same patient from time to time Extreme caution in the administration of the drug is advised

Toxic symptoms of thiocyanate therapy include fatigability drowsiness and in severe instances coma There may be anorexia nausea and even vomiting Weakness may appear and lead to faintness or collapse Psychoses and skin eruptions have been reported

Thiocyanate therapy will often relieve severe headache if proper blood levels are maintained It will often lower the blood pressure moderately though irregularly and in mild hypertension it may produce a normal blood pressure The effects of thiocyanate wear off 2 or 3 weeks after it has been withheld and the blood pressure then returns to its previous level

Veratrum viride has been used recently for its hypotensive effect but reports of its effectiveness are rather conflicting Dosage is determined empirically by administering gradually increasing doses until therapeutic or toxic effects are observed The preparation is given by mouth and the duration of effect is between 10 and 14 hours One may administer 10 Craw units (1 tablet) every 2 hours until an effect is observed and then maintain the patient on a therapeutically effective maintenance dose every 12 hours A hypotensive effect is achieved in perhaps 50 per cent of patients Symptomatic relief is apt to be greater than objective evidence of improvement Some excellent results have been reported in hypertensive encephalopathy

Toxic effects include nausea and vomiting a sense of constriction in the throat and chest excessive salivation occasional facial and peripheral paresthesias and transient blurring of vision These are encountered in perhaps one third of all patients so treated but the effects usually recede promptly upon the withholding of medication Cumulative toxic effects occur usually with daily doses of 60 or more Craw units and hypotensive effects are closely related to the toxic manifestations The intravenous injection of protoveratrine obtained from Veratrum viride is being studied at the present time

*Low Sodium Diet* —Careful observation of the effects of the low sodium diets during

treatment of impaired function of the various organs damaged by the disease

*Symptomatic Treatment* —Many symptoms of essential hypertension are psychosomatic in nature or are markedly aggravated by the reaction of the patient to the traumatic impacts of life They should be treated in exactly the same manner and with just as much attention to detail as they would be in psychoneurosis on any basis and of any origin Psychotherapy, ranging from detailed psychoanalysis to the necessarily superficial but careful inquiry into the emotional problems of the patient by the attending physician, may produce remarkable improvement in the symptoms presented Sedatives used judiciously are important adjuncts in the treatment of fatigability tension insomnia and related symptoms The barbiturates are used most frequently but sodium bromide or chloral hydrate are excellent substitutes when given in moderate doses at bedtime or in smaller doses on two or three occasions during the day

The vasospastic symptoms, such as headache, vertigo and episodes of peripheral vasospasm, may be relieved by the use of sedatives and the headache itself may respond to the use of analgesics Acetyl salicylic acid preferably in compound pills is the most commonly used agent for this purpose Experience with the sympathetic blocking agents is limited but these may be worth a trial since one of their effects is to produce hypotension

Priscoline® appears to be the most effective of these agents and is effective by mouth, which is an advantage in long term therapy Potassium thiocyanate, which is used to reduce the blood pressure itself is particularly useful in relieving the more severe and persistent headaches and attacks of dizziness This has also been claimed recently for veratrum viride and related compounds In instances where headaches and cerebral symptoms occur so violently as to constitute a crisis intramuscular injections of 50 per cent magnesium sulphate or lumbar puncture with removal of moderate amounts of spinal fluid may afford relief

Impaired cardiac function is a common cause of dyspnea Dyspnea is usually the first symptom of cardiac origin, but dyspnea may occur from other causes and must be evaluated carefully Progressive exertional dyspnea accompanied by cardiac enlargement and electrocardiograph evidence of myocardial damage is almost always due to cardiac damage resulting from hypertension Occasionally, paroxysmal nocturnal dyspnea cardiac asthma, or pulmonary edema may reveal evidence of cardiac failure early in the course of the disease

Patients suffering cardiac failure or severe myocardial damage must reduce their weight to normal if it is excessive Digitalization is indicated in overt heart failure or auricular fibrillation, mercurial diuretics and low sodium diets are necessary when there is evidence of either right- or left sided heart failure Severe dyspnea without overt heart failure often responds to a period of bed rest and a regimen of the purported coronary vasodilators—the xanthines, of which aminophyllin is the most popular

In patients with severe dyspnea and orthopnea but no gross evidence of congestive heart failure the use of the mercurial diuretics is finding increasing favor The action of these agents is often augmented by preparing the patient with ammonium chloride for several days prior to the injection of the mercurial

Nocturia associated with the inability of the kidneys to concentrate the urine indicates impaired renal function Treatment consists in maintaining an adequate intake of fluid and of protein but restricting the intake of sodium In this manner adequate fluid intake may be maintained without increasing edema formation When renal failure is severe one must be cautious lest the restriction of sodium leads to symptoms of acute sodium depletion Mercurial diuretics should not be used in advanced renal failure Anemia may occur in instances of essential hypertension complicated by renal failure and may fail to respond to any measure other than repeated blood transfusions In terminal renal insufficiency treatment is palliative Fluids and salts are replaced by small subcutaneous infusions transfusions are given for anemia calcium chloride for the tetany which may be associated with uremia and bicarbonate of soda for acidosis

*Postoperative complications of sympathectomy* include pneumothorax arising from incision of the pleura at surgery, neuritis, due to injury to the intercostal nerves, and sterility due to inability of the patient to empty the seminal vesicles. Postural hypotension on assuming the erect position is a common occurrence postoperatively in successful sympathectomy. It is accompanied by a disturbing tachycardia and may produce syncope. Ordinarily this effect becomes much less pronounced as time elapses and may disappear completely in from three to twelve months. In some instances this may persist indefinitely and prove sufficiently annoying to require the wearing of an abdominal support.

Though the mortality rate from these procedures is under 10 per cent in the best hands, one of the more common causes of death is coronary occlusion with myocardial infarction. This is thought to be a result of the sudden lowering of the blood pressure.

Sympathectomy can accomplish the following favorable effects. Blood pressure, both systolic and diastolic, may be reduced significantly, and sometimes this is permanent. The size of the heart may be reduced, and the electrocardiogram may revert from the pattern of left ventricular hypertrophy and strain to a normal tracing. Changes in the ocular fundi may regress with relief of arteriolar spasm and clearing of edema of the optic discs. It is not clear how great an improvement may occur in renal function, but the abnormal findings in the urinary sediment may disappear completely following sympathectomy. Even when there is no objective improvement there is frequently a dramatic and sustained improvement symptomatically, including the partial or complete relief of intractable headache. In many patients the improvement is of a temporary nature only.

*The selection of patients for sympathectomy* is uncertain. The edation test, various pressor tests (*e g* cold pressor test), caudal or spinal anesthesia, and the administration of sympathetic blocking agents preoperatively to patients with essential hypertension have not proved to be of any consistent value in selecting patients for sympathectomy. Careful observers have concluded that the number of patients who are suitable candidates are fewer than 10 per cent of all patients with hypertension.

Sympathectomy should not be performed for the relief of symptoms unless these are unendurable and cannot be relieved by other less heroic measures. It should be performed only by highly skilled specialists experienced in this procedure. Sympathectomy is rarely or never an emergency and so should always be preceded by painstaking evaluation of the patient and his disease.

There is no convincing evidence that the life expectancy of hypertensive patients is improved by this procedure.*

### Prognosis

Essential hypertension is ordinarily a progressive disease and the prognosis in any given case must, of necessity, be guarded. One may quote statistics at length but they are of small avail in the individual case.

The prognosis in general appears to depend on several major and several minor factors.

1) *Major Factors.*—(*a*) The extent of the arteriolar lesions can be determined most accurately by examining the retina and by determining the functional state of the kidneys.

*b*) The degree of arteriosclerosis present. Degenerative changes always occur in the larger arteries and they are more closely related to the duration of the hypertension than to its degree. Such lesions, involving especially the coronary and cerebral arteries, are frequently the factors determining the course and outcome of the disease.

*c*) The integrity of the heart, which depends on the efficiency and sufficiency of the coronary circulation.

2) *Minor Factors.*—(*a*) The height of the blood pressure.

*b*) The age at which hypertension develops. Hypertension developing in middle and old age is usually milder and more slowly progressive than is hypertension developing in early life, since in early life it tends to run a more rapid course and often terminates in the syndrome of malignant hypertension.

*Partial adrenalectomy in combination with sympathectomy has been found a useful procedure in reducing severe malignant hypertension that is otherwise intractable, but whether this procedure produces a lasting beneficial effect is not yet known. For discussion of adrenalectomy in hypertention *see* C. C. Wolferth *et al.* Ann Int Med 35 July 1951.—Editor

the past 15 years seems to warrant the following statements

1 Some patients with severe essential hypertension will respond to a very low sodium diet with a significant reduction in blood pressure and may maintain the reduction while they remain on the diet, in some cases as long as several years

2 Associated with this reduction in blood pressure the eye signs and the untoward symptoms of hypertension may disappear or markedly improve

3 It is impossible at present to predict with certainty before trial which patients will respond favorably

4 The abstinence from sodium must be rigid Halfway measures are futile

5 The rice diet probably has as its main virtue a very low sodium content It is a good basic diet to start with when placing a patient on a low-sodium regimen Additions of foods of low-sodium content can then be made under well controlled conditions

6 The physician must be alert and well versed in the numerous sources of sodium other than foodstuffs which often vitiate the low-sodium diet including certain tooth pastes carbonated drinks and various medications

7 Many patients will not remain on the low sodium diets for protracted periods of time but, for permanent results the diet must be maintained

*General Medical Measures* —Regardless of whether hypertension produces symptoms in a given case and regardless of other forms of therapy the following measures should be incorporated into the regimen prescribed for patients with hypertension

1) Psychic factors should be controlled by adequate physical and mental relaxation including restricted hours of work rest periods before meals and at least 8 hours of sleep nightly Noncompetitive hobbies are desirable for many patients and frequent vacations of considerable length should be taken when possible

2) Any and all activities which produce sudden and considerable elevations of the blood pressure should be avoided—including swimming in cold water competitive sports activities which require great and sudden effort such as lifting, pushing, or squeezing The best form of physical exercise for the hypertensive patient is walking at a normal moderate pace

3) Weight reduction is always desirable in hypertensive patients who are obese It will not reduce the blood pressure in essential hypertension unless carried to the point of producing emaciation and debilitation, but it does improve the patient's ability to perform ordinary activities without dyspnea and discomfort The ideal weight for the average hypertensive is within the low normal range Weight reduction should be done slowly and not at the expense of restricting protein intake Despite current experimental work, there is no evidence that the restriction of cholesterol in the diet produces any modification in the course of clinical hypertension Fluid should not be restricted and, if edema occurs it should be controlled by the restriction of the sodium ion in the diet

4) Alcohol in moderation is probably advantageous because of its ability to produce generalized vasodilatation and to enable the patient to relax Excesses should not be permitted, however Tobacco in moderation has not been shown to be of any particular harm though it does provoke peripheral vasoconstriction and should be limited in quantity Beverages such as coffee and tea are permissible in moderation

### SYMPATHECTOMY

Sympathectomy is not curative in the sense of removing the cause since this is not known but it does produce considerable benefit in the relief of symptoms and appears to prolong the life of some hypertensive persons

The operative procedures have been varied and numerous, but have evolved during the past two decades from excisions of a relatively few sympathetic ganglia to almost complete bilateral sympathectomy Before this surgical therapeutic approach can be evaluated completely it will be necessary to study the postoperative course of a very large number of hypertensive patients for the duration of their lives a matter of probably a generation

of the patient are often beneficial since these patients often exhibit poor muscular development, undernutrition poor muscle tone and faulty posture In many instances the problem is purely psychosomatic

Drugs should not be administered to increase the blood pressure Sedation may be indicated for the highly nervous individual

*Prognosis* —The prognosis is excellent and the life expectancy of patients with constitutional hypotension is better than that of the general population

## ORTHOSTATIC HYPOTENSION

### (*Postural Hypotension*)

In most persons the rapid change of position from the recumbent to the erect may be accompanied at times by a feeling of giddiness or faintness due to the redistribution of blood in the vascular system as a result of the change of posture In patients with orthostatic hypotension this effect is accentuated so that faintness or actual syncope occur regularly upon such changes of position

*Etiology* —Change of position from the recumbent to the erect is accompanied by a redistribution of blood within the vascular system In the erect position the force of gravity increases the volume of blood in the lower portion of the body at the expense of the cerebral blood flow Cerebral anemia of any significant degree is prevented ordinarily by the intervention of vasoconstrictor reflexes and by a slight increase in the heart rate In the average individual only minor and transient changes of blood pressure occur with change of position In the patient with orthostatic hypotension the compensatory mechanisms are disturbed blood pressure changes are exaggerated and symptoms arise The impaired vasomotor response is frequently evident also by disturbances in sweating That the parasympathetic nerves are involved also is suggested by the depression of vagal response to alterations in blood pressure and to the administration of atropine Pooling of the blood in the dependent portions of the body is believed to take place in the venous side of the circulation

*Symptoms* —The following features are common to the majority of patients with orthostatic hypotension (1) a sharp decrease in both systolic and diastolic blood pressures with fainting or marked weakness upon assuming the erect position (2) diminished sweating which may be localized (3) failure of the pulse to accelerate sharply upon standing (4) accentuation of symptoms during hot weather (5) increased urinary output during recumbency Other features seen often in cases of orthostatic hypotension include (1) pallor, (2) youthful visage for actual age (3) tendency for B M R to be low (4) loss of libido with or without impotence (5) central nervous system disturbances and (6) blood urea elevated to the upper limits of normal

*Treatment* —Treatment of orthostatic hypotension consists of the administration of drugs which will prevent the fall of blood pressure to low levels when the patient stands The following drugs and dosage schedules are commonly employed

- Ephedrine sulphate 50 mg every 2 hours
- Benzedrine sulphate 20 mg upon awakening and 10 mg during the day
- Paredrine 40 mg

Doses are ordinarily given upon awakening and every two hours through the active portion of the day These drugs may have undesirable side reactions which must be taken into consideration when thinking of prolonged administration They should not be given after late afternoon since they may then interfere with nocturnal sleep

Sleeping with the head of the bed elevated from 6 to 18 inches on bed blocks is often helpful in ameliorating symptoms especially those which occur upon arising

The wearing of an abdominal belt may be of value in visceroptotic persons in preventing the pooling of blood in the splanchnic areas

## FUNCTIONAL OR VASOMOTOR DISTURBANCES

Vasomotor disturbances of the circulation are of two general types—those in which there is excessive vasoconstriction (vaso-

c) Sex Women develop atherosclerosis later in life than do men and the lesions are apt to be less severe

Because hypertensive patients (a) usually exhibit symptoms and signs arising from involvement of more than one organ, (b) frequently have one or more complicating diseases, and (c) frequently die following the onset of failure of more than one vital organ, the cause of death is often not clear However, it is generally accepted that 50 per cent of the patients with hypertension die of congestive heart failure 15 per cent die of coronary sclerosis, 15 per cent die of cerebrovascular accidents 8 per cent die of uremia, and the rest die of unrelated causes

According to Keith, the mortality among patients who have hypertension of grades I and II is 30 and 42 per cent respectively, within 4 years, among patients in group III, 78 per cent and in group IV 98 per cent

## HYPOTENSION

### (Low Blood Pressure)

The lower limits of normal for the blood pressure are less well defined than are the upper limits As a rule, the diagnosis of hypotension should not be made unless the patient exhibits a systolic pressure of not more than 100 mm Hg It is to be remembered that the normal systolic blood pressure at birth is between 50 and 60 *mm Hg* and though it rises gradually it does not exceed 100 mm until puberty

Hypotension may be discussed conveniently under three categories (1) symptomatic hypotension which is encountered in the course of a variety of diseases (2) constitutional hypotension permanently low blood pressure occurring in healthy adults and often familial in nature and (3) orthostatic hypotension the fall of blood pressure which occurs upon changing from the horizontal to the erect position

## SYMPTOMATIC HYPOTENSION

### (Secondary Hypotension)

Acute symptomatic hypotension often of a severe degree occurs in Addison s disease in Simmonds disease (hypophyseal cachexia) *in shock in circulatory collapse*, and during and after in any severe infectious diseases It is a common result of myocardial infarction or pulmonary embolism *A less severe form is seen in chronic debilitating* diseases such as pulmonary emphysema bronchial asthma and pulmonary tuberculosis It is seen almost always in *patients cachectic from any cause Hypotension* is one of the important diagnostic criteria for Addison s disease which should be suspected in the presence of persistent *hypotension below 80 mm Hg*

## CONSTITUTIONAL HYPOTENSION

### (Essential Hypotension)

About 3 per cent of healthy adults exhibit a low blood pressure which is usually symptomless and discovered accidentally when the pressure is taken in a physician s office It is wise to avoid emphasizing the fact that the blood pressure is low since many of these patients are neurasthenic and will utilize this unimportant finding as a basis for subsequent complaints

*Pathology* —A majority of patients with this type of hypotension conform to a constitutional type (1) thin asthenic habitus (2) small heart (3) visceroptosis (4) cold, clammy extremities (5) poor vasomotor reactions (6) sometimes postural hypotension (7) poor resistance to infection (8) a normally functioning cardiovascular system At autopsy they are shown to have small hypoplastic hearts

*Symptoms* —Many patients with this type of hypotension complain of lassitude fatigability vertigo inability to concentrate mentally palpitation coldness and sweating of the hands and feet general chilliness and headache It is almost never possible to associate these symptoms with any abnormality other than the presence of hypotension It is significant that this condition is much more common among females than among males This condition is frequently classified as neurocirculatory asthenia

*Treatment* —Medical treatment is nonspecific If the patient is aware of his hypotension he should be reassured concerning its significance Measures designed to improve the general psychic and physical status

of the patient are often beneficial since these patients often exhibit poor muscular development undernutrition poor muscle tone and faulty posture In many instances, the problem is purely psychosomatic

Drugs should not be administered to increase the blood pressure Sedation may be indicated for the highly nervous individual

*Prognosis* — The prognosis is excellent and the life expectancy of patients with constitutional hypotension is better than that of the general population

## ORTHOSTATIC HYPOTENSION
### (Postural Hypotension)

In most persons, the rapid change of position from the recumbent to the erect may be accompanied at times by a feeling of giddiness or faintness due to the redistribution of blood in the vascular system as a result of the change of posture In patients with *orthostatic hypotension* this effect is accentuated so that faintness or actual syncope occur regularly upon such changes of position

*Etiology* —Change of position from the recumbent to the erect is accompanied by a redistribution of blood within the vascular system In the erect position the force of gravity increases the volume of blood in the lower portion of the body at the expense of the cerebral blood flow Cerebral anemia of any significant degree is prevented ordinarily by the intervention of vasoconstrictor reflexes and by a slight increase in the heart rate In the average individual only minor and transient changes of blood pressure occur with change of position In the patient with orthostatic hypotension the compensatory mechanisms are disturbed blood pressure changes are exaggerated and symptoms arise The impaired vasomotor response is frequently evident also by disturbances in sweating That the parasympathetic nerves are involved also is suggested by the depression of vagal response to alterations in blood pressure and to the administration of atropine Pooling of the blood in the dependent portions of the body is believed to take place in the venous side of the circulation

*Symptoms* —The following features are common to the majority of patients with orthostatic hypotension (1) a sharp decrease in both systolic and diastolic blood pressures with fainting or marked weakness upon assuming the erect position (2) diminished sweating which may be localized (3) failure of the pulse to accelerate sharply upon standing (4) accentuation of symptoms during hot weather, (5) increased urinary output during recumbency Other features seen often in cases of orthostatic hypotension include (1) pallor (2) youthful visage for actual age (3) tendency for B M R to be low (4) loss of libido with or without impotence (5) central nervous system disturbances and (6) blood urea elevated to the upper limits of normal

*Treatment* —Treatment of orthostatic hypotension consists of the administration of drugs which will prevent the fall of blood pressure to low levels when the patient stands The following drugs and dosage schedules are commonly employed

- Ephedrine sulphate 50 mg every 2 hours
- Benzedrine sulphate 20 mg upon awakening and 10 mg during the day
- Paredrine 40 mg

Doses are ordinarily given upon awakening and every two hours through the active portion of the day These drugs may have undesirable side reactions which must be taken into consideration when thinking of prolonged administration They should not be given after late afternoon since they may then interfere with nocturnal sleep

Sleeping with the head of the bed elevated from 6 to 18 inches on bed blocks is often helpful in ameliorating symptoms especially those which occur upon arising

The wearing of an abdominal belt may be of value in visceroptotic persons in preventing the pooling of blood in the splanchnic areas

## FUNCTIONAL OR VASOMOTOR DISTURBANCES

Vasomotor disturbances of the circulation are of two general types—those in which there is excessive vasoconstriction (vaso

spastic) and those in which there is excessive vasodilatation The commonest and most striking signs in the vasomotor disturbances are alterations in the color and temperature of the skin Such changes also occur in the organic peripheral vascular disease but are apt to be less striking and are usually accompanied by other signs and symptoms which *command attention*

The color of the skin is largely determined by the size and number of capillaries and venules the temperature depends upon the caliber of the arterioles When vasomotor reactions occur excessively and persistently, a disease state results Vasomotor disturbances may lead eventually to organic changes and to complications common to the organic arterial diseases

## VASOSPASTIC (VASOCONSTRICTOR) DISTURBANCES

A Raynaud s disease (primary or idiopathic Raynaud s syndrome)

B Raynaud s syndrome (secondary)

1 Traumatic vasospastic syndrome pneumatic hammer disease other types of repeated trauma as those resulting from the practice of stenography, piano playing, *etc* post traumatic or postoperative states with or without Sudeck s atrophy

2 Neurogenic secondary to c n s * disease spondylitis cervical rib neurovascular syndromes of the shoulder neuritis *etc*

3 Organic vascular disease secondary to arteriosclerosis obliterans thromboangiitis obliterans syphilitic arteritis embolism

4 Intoxications those caused by nicotine arsenic ergot (early) lead and other heavy metals

5 Miscellaneous diseases scleroderma lupus erythematosus paroxysmal hemoglobinuria, polycythemia vera

C Acrocyanosis

D Cutis Marmorata (early livedo reticularis)

E Vasospasm secondary to

1 *Lesions of c n s or peripheral nerves*

2 Thrombophlebitis

3 Acute arterial occlusion

4 Post traumatic osteoporosis

## RAYNAUD S DISEASE AND RAYNAUD S SYNDROME

(Raynaud s Phenomenon)

Raynaud s phenomenon consists of episodes of constriction of the smaller arteries and arterioles of the extremities resulting in intermittent changes in the color of the skin Classically there is pallor, cyanosis or both during the period of vasoconstriction, and usually intense rubor during the period of reactive hyperemia Raynaud's disease *refers to Raynaud s phenomenon occurring* without an associated and predisposing disease

The *criteria for making a diagnosis of* Raynaud s disease are (1) episodes of Raynaud s phenomenon excited by cold or emotion (2) bilateral involvement, (3) absence of gangrene beyond minimal cutaneous areas (4) absence of any associated, predisposing disease, (5) the history of symptoms for at least 2 years Secondary Raynaud s phenonemon occurs in association with and as a result of some primary organic *disease or some other specific stimulation* such as percussive trauma

The importance of the nosological distinction is as follows The term *Raynaud s phenomenon* may be used to describe succinctly the classical series of color and temperature changes which occur in the digits under a variety of circumstances and as a result of a variety of causes It is a descriptive term and does not imply recurrence nor does it suggest etiology When the phenomenon recurs as a result of some associated condition, it may then be called *Raynaud s syndrome* and may be used in conjunction with the term for the primary cause, as for example thromboangiitis obliterans with Raynaud s syndrome When the phenomenon is *recurrent and painstaking* investigation reveals a typical syndrome

* c n s —(central nervous system)

without apparent primary cause the condition may be classified as Raynaud's disease

## Etiology

The fundamental cause of Raynaud's syndrome is not known but certain stimuli are capable of initiating individual attacks

1) *Cold*—Cold is the principal factor in precipitating attacks of Raynaud's syndrome In the susceptible individual exposure to cold of a sufficient degree results in the development of vasospasm in the affected areas and this spasm is not relieved until the environmental temperature is increased The degree of cold necessary to produce an attack varies from individual to individual in highly susceptible individuals it may be between 56 and 70° F (13 3–21 1° C) Immersion of the hand in a basin of ice water, a common test for provoking vasospasm may not induce attacks but sufficient exposure of the body to cold air to cause generalized chilling will almost always induce the clinical phenomenon

Raynaud's syndrome is ordinarily more troublesome in winter than in summer and in colder temperate climates than in the tropics In severe cases however episodes may occur upon sudden drops in temperature in even warm climates

2) *Emotion*—Anger excitement and fear may precipitate attacks in susceptible individuals In some the effects of emotion aggravate the effect of cold in other patients emotional stimuli alone even in a warm environment are sufficient to precipitate attacks of vasospasm

3) *Traumatic Vasospastic Disease*—Traumatic vasospastic disease occurs in persons who use vibrating tools such as pneumatic hammers (pneumatic hammer disease) and also in those who do certain types of skilled work which subject the fingers to repeated though often mild trauma—for example stenographers concert pianists handball players and switchboard operators Vasospastic phenomena usually occur as long as the person persists in the occupation if this is not avoided the condition may become progressive and irreversible

4) *Occlusive Arterial Disease*—Raynaud's syndrome is relatively common during the early stages of thromboangiitis obliterans and may occur with arteriosclerosis obliterans As the organic disease progresses the vasospastic component usually diminishes

5) We have recently noted a high coincidence of the Raynaud's phenomenon and the hyperabduction syndrome of the shoulder girdle It may also accompany the cervical rib and scalenus anticus syndromes The exact interrelation of these conditions is as yet not completely understood

## Incidence

Raynaud's disease is predominantly a disease of women in a ratio of at least 3 to 1 In any instance of Raynaud's phenomenon in the male a primary disease is likely to be present This is not however always the case Raynaud's disease ordinarily appears during the early decades of life three-quarters of the patients manifest symptoms before the age of 40 years Raynaud's phenomenon appearing during later decades is usually a complication of organic vascular changes The sex and age incidence of secondary Raynaud's phenomenon is that of the primary or predisposing disease or trauma

## Pathology

The earlier stages of Raynaud's syndrome are purely vasomotor in nature and no structural changes are to be observed Later there are local thickenings in the walls of the smaller arteries and occlusions presumably due to repeated vasospastic insults Occlusion is unusual in vessels larger in diameter than those of the digits Eventually there is striking dilatation of the capillary bed as demonstrable in the capillaries of the nailfolds

Gangrene occurs only in advanced cases and is confined to limited cutaneous areas most commonly the tips of the digits Gangrene probably results from the combined effects of repeated vasospasm and organic occlusion It is not necessary for gangrene or trophic changes to be present to make the diagnosis as was suggested in Raynaud's original reports he apparently confused thromboangiitis obliterans with

what we now know as the true Raynaud's syndrome

During an attack, arteriolar spasm prevents blood from entering the capillaries During the stage of waxy pallor the capillaries are collapsed and empty, or interrupted, and the small amount of blood in them is stagnated The surface temperature of the involved area falls to approximate room temperature Later, there is a reflux of blood into the dilated capillaries from the venous side Stasis of this blood produces the deep cyanosis which often follows the stage of pallor With relief of the attack the arterioles open widely filling the capillaries and venules with oxygenated blood The involved areas become bright red and the surface temperature rises to above normal during this phase This may appear in a patchy distribution as the vessels open progressively

## Clinical

*Typical Clinical Picture* —Usually the patient is a young woman who has observed the classical color changes in her fingers upon exposure to cold Ordinarily the changes have developed gradually, but occasionally there has been a dramatic onset with the sudden appearance of an acute episode of pallor—the dead finger phenomenon' Early only a single digit may be involved but usually within a year or two the tips of the fingers in both hands become involved The color changes may consist only of pallor or cyanosis or both They usually include the phase of reactive hyperemia or rubor

Symptoms are worse during the cold season While pain is not prominent paresthesias (numbness burning tingling tightness pins and needles) are common During the attack the fingers are cold sensation may be impaired and there may be swelling which occasionally persists between attacks As the condition advances attacks become more frequent and more severe They may occur with the slightest cooling or upon the mildest emotional upset so that warm weather affords no relief

The fingers are involved in over 90 per cent of cases of Raynaud's disease the toes in slightly more than half the cases The nose, ears, and cheeks may be involved In the secondary form, the upper extremities are involved in the majority of cases The possibility that the Raynaud's phenomenon is a part of a drug reaction must be kept in mind during the taking of the history Skin eruptions and other stigmata of drug reactions should be sought Arthritis and edema occur in a few instances and should arouse a suspicion of lupus erythematosus and other collagenous diseases The occupational history is frequently important and may establish the diagnosis and etiology

## Physical Findings

Inspection of the extremities and particularly of the digits must be painstaking Trophic changes and early gangrene of the skin should be noted If possible an attack should be provoked and observed directly to determine the nature extent and duration of the changes which occur The effect of an emotional disturbance in provoking an attack should also be noted

It is important to identify the presence of any primary disease Occlusive arterial disease should be sought by palpation of the peripheral arteries by examination for postural color changes and by oscillometry Careful neurological examination must include testing of the reflexes The patient must be studied carefully for a possible neurovascular syndrome of the shoulder girdle In the presence of scleroderma the extent and duration of the sclerodermatous changes must be investigated carefully to determine whether the scleroderma is primary or secondary

## Course

The course of Raynaud's syndrome may range from very mild to severe In the former there is nonprogressive involvement of one or two digits occurring infrequently and only in response to severe cold or emotional upset In the latter there is steady progression involving not only the fingers and/or the toes but the hands or feet and even face as well there are also more frequent attacks precipitated by ever

TABLE 48.—DIFFERENTIAL DIAGNOSIS BETWEEN RAYNAUD'S DISEASE, ACROCYANOSIS, LIVEDO RETICULARIS, PERNIO AND ACROSCLERODERMA

| | *Raynaud's disease* | *Acrocyanosis* | *Livedo reticularis* | *Pernio (erythrocyanosis)* | *Acroscleroderma* |
|---|---|---|---|---|---|
| Age and sex | 70% of cases in girls and young women | 90% of cases in girls and young women | In either sex at any age | 70% of cases in young women | 85% of cases in young women |
| Type of color change | Mottled or diffuse white, blue, red | Diffuse blue | Mottled and reticulated red and blue | Localized red and blue | White, blue and red, mottled or diffuse |
| Location of symptoms | Fingers and toes, rarely nose and ears | Usually hands, occasionally feet | Usually legs, occasionally arms | On exposed surface, esp. legs | Hands and feet |
| Persistence of symptoms | Intermittent | Permanent | Permanent | Variable but aggravated in winter | Intermittent |
| Local symptoms | Burning pain if any | Usually none | Pain and coldness if any | Severe itching and burning | Stiffness and tension of skin |
| Effects of cold | Aggravates symptoms | Aggravates symptoms | Accentuates blueness | Increases redness | Symptoms aggravated |
| Effects of heat and vasodilatation | Decreases color changes greatly | Little change | Decreases blueness | Increases redness | Decreases color changes |
| Effects of posture and exercise | Little change | Elevation decreases cyanosis | Elevation or exercise decrease cyanosis | No change | No change |
| Necrosis and ulceration | Slight and limited if any | None | Only in severe cases | Commonly in severe cases | Frequent in advanced scleroderma |

TABLE 49.—THE DIFFERENTIAL DIAGNOSIS BETWEEN RAYNAUD'S DISEASE AND THE OCCLUSIVE ARTERIAL DISEASES, THROMBOANGIITIS OBLITERANS AND ARTERIOSCLEROSIS OBLITERANS

| | *Raynaud's Disease* | *Thromboangiitis Obliterans* | *Arteriosclerosis Obliterans* |
|---|---|---|---|
| Sex | More than 75% of cases are female | More than 95% of cases are male | More than 85% of cases are male |
| Age at onset (in years) | From puberty to 50 | From 20 to 40 | More than 50 |
| Raynaud's phenomenon | 100% of cases | About one third of cases | Uncommon, about 10% of cases |
| Postural color changes | Absent | Commonly present | Commonly present |
| Gangrene (if present) | Limited to small areas of skin | Minimal to extensive | Minimal to extensive |
| Involvement of upper limb | In almost all cases | In less than half of cases | Rare |
| Involvement of lower limb | Frequent but less so than in upper limb | In more than 95% of cases | In 100% of cases |
| Symmetry of involvement | Bilateral and symmetrical | Asymmetrical but usually bilateral | Asymmetrical but usually bilateral |
| Peripheral arterial pulsations | Palpable | Impaired or absent | Impaired or absent |
| Calcified arteries | Absent | Usually absent | Usually present |
| Superficial phlebitis | Unusual | Occurs in nearly one half of cases | Unusual |
| Acrosclerodema | May occur | Absent | Absent |

milder stimuli, and often the appearance of trophic changes and gangrene. Necrosis, ulceration and gangrene may occur in the absence of any demonstrable organic change in the vessels.

### Diagnosis

A typical attack of Raynaud's phenomenon is ordinarily sufficiently characteristic to establish the diagnosis. The differentiation between the Raynaud's disease and secondary Raynaud's syndrome may be more difficult. The demonstration of a causal primary disease may require observation of the patient over a period of time.

### Complications

Sclerodermatous changes, either primary or secondary to the Raynaud's phenomenon, may interfere with the use of the involved extremities, especially with the use of the fingers. Ulceration and gangrene of the tips of the digits cause discomfort, pain and loss of function. Only rarely does secondary infection become so severe as to require amputation of a digit. In some instances such infection involves the bones of the phalanges.

### Differential Diagnosis

The differential diagnosis between Raynaud's syndrome and the various vascular conditions with which it may be confused appears in the following tables.

### Treatment

Medical.—(1) *Protection Against Cold.*—The patient with Raynaud's syndrome must be protected carefully against cold. He should live in a warm climate, particularly during the winter. If outdoor activities cannot be avoided completely during cold weather, warm clothing is essential. Shoes should be sufficiently large to permit the patient to wear one or two pairs of woolen socks. Automobiles used by the patient should be heated. Fur lined gloves and lined galoshes should be worn out-of-doors. The patient should be instructed to maintain the warmth of the body, since cooling of the trunk, regardless of the temperature of the limbs, may cause reflex vasospasm in the extremities. The avoidance of cold will not prevent attacks entirely where emotional or other contributory factors persist.

2) *Tobacco.*—It is probably wiser to omit tobacco in most cases, since smoking causes vasoconstriction and repeated attacks of vasoconstriction lead to permanent structural damage to the smaller vessels. In patients with mild disease and whose habit of smoking is strongly established, temperature studies of the finger tips may be made to demonstrate how important a role smoking plays. It should be noted that smoking *per se* does not have the specific aggravating effect in Raynaud's syndrome which it has in thromboangiitis obliterans.

3) *Psychiatric.*—Many patients with Raynaud's syndrome have unstable vasomotor systems. Psychiatric evaluation and treatment of such patients is often of distinct value in treating Raynaud's phenomenon. Many are dreadfully afraid that their illness will result in the loss of digits or limbs. Reassurance is important. Many cases do not progress for decades. The patient may be warned, however, that his condition may ultimately become more disturbing and sympathectomy be necessary.

4) *Pain.*—Pain is usually not notable in Raynaud's syndrome, although discomfort may be intense during attacks of acute vasospasm. Simple warming of the body and of the hands will ordinarily relieve the average patient. Alcohol in the form of whiskey or brandy may be taken to hasten relief. Papaverine hydrochloride taken orally in doses of from 0.1 to 0.2 grams or Priscoline® 25 mg. may be prescribed every four hours during periods of exposure to cold. Papaverine may be given intravenously in doses of from .06 to .12 grams if necessary.

5) *Care of Involved Areas.*—Overheating an area of skin involved in vasospasm may produce serious burns because the circulation cannot carry off heat and metabolic wastes during the period of vasospasm. Warming of involved digits and limbs must be gradual and never excessive. Strong antiseptics must not be applied to superficial lesions of the ischemic tissues for fear of injury. The ulcers of Raynaud's syndrome heal best

when dry. If infected they may be soaked in *warm not hot* (temp 95° F) packs of normal saline or penicillin solution for an hour once or twice a day. Wet dressings must not be allowed to cool since chilling produces vasospasm.

6) *Adrenolytic and Sympatholytic Drugs*.—Tetraethylammonium chloride (Etamon) and bromide, dibenamine and Priscoline* have been used extensively during the past two years. Dibenamine has the disadvantage of requiring intravenous injection. The results of treatment with the tetraethylammonium ion have been disappointing because of the relatively fleeting action of the drug. The results reported with the use of Priscoline* are much more promising.

Priscoline* may be given orally, intramuscularly or intravenously. Its effect persists for from three to eight hours. It is usually administered in doses of from 25 to 75 mg at intervals of four hours. Larger doses are best avoided since they may produce acute attacks of hypotension. It appears to diminish (but not eliminate) attacks in some patients.

7) *Hormones*.—If Raynaud's syndrome first appears during pregnancy or is aggravated during menstruation or at the menopause, estrogenic therapy should be tried. Favorable results have been reported by L. V. Allen and his co-workers.

SURGICAL.—In mild and nonprogressive Raynaud's syndrome sympathectomy is not indicated. The patient should not be operated upon until observed over a period of months, preferably through one or more winters. If Raynaud's syndrome recurs each winter, especially if the attacks are severe, one may anticipate increasingly severe and more frequent attacks and eventually trophic changes and scleroderma. Sympathectomy is then indicated to reduce disability during the cold seasons and to prevent the development of ulceration and scleroderma. Residence in a warm climate may be tried in an effort to avoid surgery.

In selecting patients for sympathectomy, it is desirable first to try a course of one of the sympathetic blocking agents or perform sympathetic blocks by the injection of novocaine. It may be realized, however, that these preliminary procedures are not reliable indications of the value of sympathectomy, which should not be withheld from a patient because he does not respond favorably to them.

Sympathectomy for Raynaud's syndrome affecting the lower extremities is usually successful, but one cannot predict the benefit of sympathectomy to the upper extremities. This is unfortunate because of the predilection of Raynaud's syndrome for the upper limbs. Failure of sympathectomy is usually due to the failure to interrupt all sympathetic fibers leading to the involved limb. This may be because unknown pathways may carry sympathetic impulses. In all instances, sympathetic ganglionectomy and resection of the sympathetic trunks should be done.

The immediate improvement, including improved skin temperature of the involved areas, relief of subjective symptoms and healing of ulcers, may be short lived. The late results depend on the completeness of the operation, the stage of the disease at the time of operation and other factors not yet clear. No conclusion should be drawn until the patient has been observed postoperatively for several years. In late cases, especially those complicated by scleroderma, the results are rarely good.

## ACROCYANOSIS

Acrocyanosis is a condition characterized by painless and persistent coldness and cyanosis of the distal parts of the extremities. It is a benign condition, ordinarily innocuous except for mild discomfort and the annoyance of its appearance. Acrocyanosis is usually not progressive. It is important clinically to differentiate acrocyanosis from Raynaud's phenomenon.

*Etiology*.—The cause of acrocyanosis is not known. The color changes have been ascribed to dysfunction of the sympathetic nervous system, since patients exhibiting the phenomenon frequently have a family history of vasomotor instability. The work of Lewis and Landis, however, indicates that the essential fault is local.

*Pathology*.—The changes of acrocyanosis are not clearly known, but several observers have described distended and enlarged capil-

laries and venules. The capillaries are longer and wider than normal and become convoluted and tortuous. The physiological changes are also obscure. Elevation of the limb fails to reveal any evidence of obstruction to the venous drainage. The larger arteries are normal. These findings indicate that the fault must lie in the arterioles or in the capillaries and venules.

*Clinical.*—The usual patient has noted continuous coldness and cyanosis of the fingers and hands for a period of years. The toes and feet may have been involved to a lesser extent. Although the changes in color and temperature may be exaggerated during the winter months, they are present even in a warm environment. There are no episodes of blanching. Rubor is not usual though it may occur in a very warm environment. There may be some swelling of the involved parts and pain may occur in moderation. In the usual case there is no evidence of occlusive arterial disease. Marked sweating of the cool cyanotic extremities is very common and distressing.

*Course.*—The course of acrocyanosis is benign and nonprogressive. Trophic changes, scleroderma, and ulceration do not occur.

*Diagnosis.*—The diagnosis is ordinarily *not difficult. The nature, extent, and location* of the color changes are ordinarily typical and do not occur in the cyclic progression—pallor to cyanosis to rubor—so characteristic of Raynaud's phenomenon.

*Laboratory.*—Capillary microscopy can be done where facilities permit but is not ordinarily necessary.

*Treatment.*—Since acrocyanosis is innocuous and nonprogressive, treatment is ordinarily restricted to protection of the patient from the effects of cold. In severe cases, sympathectomy may be performed with the probability that the results will be somewhat better than those attained in Raynaud's syndrome.

*Prognosis.*—Since there are no sequellae or complications, the prognosis for the life of the tissues is good, but complete cures are not very common.

## ACUTE ARTERIAL VASOSPASM

### (Traumatic Arteriospasm, Segmental Arteriospasm)

Acute arteriospasm, involving an entire limb, or confined to a portion thereof, frequently follows gunshot wounds, fractures, and vascular injuries and may follow relatively minor trauma. It is present, to a degree, in all instances of organic arterial occlusion due *to thrombosis or embolism* and occurs occasionally in association with acute thrombophlebitis.

Arteriospasm may persist in a chronic form and be associated eventually with Sudeck's atrophy, a demineralization of the bone secondary to vasospasm.

*Etiology.*—The exact mechanism of development is not known, but acute arteriospasm is undoubtedly due to reflex sympathetic action. Trauma to the vessels themselves is not essential, since injury to skeletal or nerve by soft tissue structures may produce profound vasospastic effects.

*Pathology.*—In the walls of the involved vessels, there are no pathological changes due to arteriospasm *per se*. Thrombosis may occur within the lumina of the vessels if the vasospasm persists over a prolonged period of time.

*Clinical.*—The symptoms and signs of acute arteriospasm are similar to those of an acute or subacute organic *arterial occlusion*. The extent and the degree of the findings depend on the size and location of the involved vessels. When large arteries are involved, the clinical picture may be identical with that of sudden organic arterial occlusion. Unless the major vessel is explored, it is often difficult or impossible to determine whether there is an intravascular clot. Delayed recognition is not usually difficult if the spasm subsides.

Reflex vasospasm is of great importance in connection with organic occlusion of a major artery, since the spasm may involve *not only the segment of the artery* which is occluded but also the entire vessel, the arterial tree served by the major vessel, the collateral circulatory channels, or the major vessels of the entire limb. Recognition of the factor of spasm is of vital importance since it may often be relieved by measures

short of exploring the major artery and its relief may completely alter the clinical picture

*Treatment* —The treatment of acute arteriospasm of a reflex nature falls into three categories (1) treatment of the underlying disease or injury (2) treatment of organic arterial occlusion and (3) relief of the arteriospasm itself

Treatment of the primary condition consists of (1) immobilization of the affected limb (2) relief of pain (3) support of the systemic circulation to prevent failure (4) reflex heat (5) sympathetic blocks or sympathectomy and (6) corrective surgery for the original injury (if indicated)

When organic occlusion on the basis of thrombosis or embolism is present anticoagulants should be administered and consideration given to the possibility of surgical removal of the intravascular clot Relief of pain by immobilization of an injured extremity and by the administration of adequate amounts of codeine or morphine may in itself relieve milder degrees of arteriospasm Since the circulation to the extremity is impaired nothing should be done to increase the metabolism of the involved member The application of heat greater than that of normal body temperature is to be avoided

Measures directed toward the relief of the arteriospasm fall into three categories (1) the administration of drugs which relieve vasospasm (2) the blocking of the sympathetic trunks by the injection of novocaine and (3) sympathectomy The first and second methods should be given adequate trial before surgery is considered The time honored use of papaverine intravenously in doses of from 0 3 to 0 6 grams followed every four hours by the administration of from 0 6 to 12 grams orally may be supplemented by the use of the sympatholytic drugs Papaverine is even more striking in its effects when given into the artery supplying the affected limb The agent currently in favor is Priscoline® It may be given parenterally in doses of from 75 to 100 mg and followed up with oral doses at intervals of four hours If a salutory effect is not obtained in from four to eight hours a sympathetic block should be performed If this is successful additional blocks may be performed once or twice each day until the spasm is completely and permanently relieved Sympathectomy is necessary only when these measures fail but should not be postponed unduly for persistent arteriospasm is distinctly damaging to all tissues supplied by the affected vessel

## VASODILATOR DISTURBANCES—ERYTHERMALGIA

(Erythromelalgia)

Vasodilator disturbances are much less common than vasospastic conditions A well-defined syndrome is erythermalgia (erythromelalgia or Weir Mitchell's disease) which consists of the classical triad redness pain and an increase in the temperature of the involved area It does not include the painful red but *cold* extremity of the occlusive arterial disease called *erythralgia* or, preferably *painful rubor*

*Etiology* —The etiology of erythermalgia is not known It may occur as a primary or idiopathic condition or as a secondary symptom-complex of some other vascular disease as indicated in the following table

Etiological Classification of Erythermalgia (Erythromelalgia)

I Erythermalgia (Erythromelalgia)—primary
II Erythermalgia (Erythromelalgia)— secondary to
  A Polycythemia vera
  B Hypertension
  C Arteriosclerosis
  D Diabetes mellitus
  E Gout
  F Thromboangiitis obliterans
  G Organic neurologic disease
  H Trauma
  I Heavy metal poisoning—*e g* with thallium mercury arsenic
  J Miscellaneous—secondary to fever hyperthyroidism alcoholism neurocirculatory asthenia menopause

*Incidence* —Erythermalgia may appear in persons of any age though it most commonly appears in adults It is equally common among men and women

laries and venules. The capillaries are longer and wider than normal and become convoluted and tortuous. The physiological changes are also obscure. Elevation of the limb fails to reveal any evidence of obstruction to the venous drainage. The larger arteries are normal. These findings indicate that the fault must lie in the arterioles, or in the capillaries and venules.

*Clinical.*—The usual patient has noted continuous coldness and cyanosis of the fingers and hands for a period of years. The toes and feet may have been involved to a lesser extent. Although the changes in color and temperature may be exaggerated during the winter months, they are present even in a warm environment. There are no episodes of blanching. Rubor is not usual though it may occur in a very warm environment. There may be some swelling of the involved parts and pain may occur in moderation. In the usual case there is no evidence of occlusive arterial disease. Marked sweating of the cool cyanotic extremities is very common and distressing.

*Course.*—The course of acrocyanosis is benign and nonprogressive. Trophic changes, scleroderma, and ulceration do not occur.

*Diagnosis.*—The diagnosis is ordinarily not difficult. The nature, extent, and location of the color changes are ordinarily typical and do not occur in the cyclic progression—pallor to cyanosis to rubor—so characteristic of Raynaud's phenomenon.

*Laboratory.*—Capillary microscopy can be done where facilities permit but is not ordinarily necessary.

*Treatment.*—Since acrocyanosis is innocuous and nonprogressive, treatment is ordinarily restricted to protection of the patient from the effects of cold. In severe cases, sympathectomy may be performed with the probability that the results will be somewhat better than those attained in Raynaud's syndrome.

*Prognosis.*—Since there are no sequellæ or complications, the prognosis for the life of the tissues is good, but complete cures are not very common.

## ACUTE ARTERIAL VASOSPASM

(Traumatic Arteriospasm; Segmental Arteriospasm)

Acute arteriospasm involving an entire limb or confined to a portion thereof, frequently follows gunshot wounds, fractures, and vascular injuries and may follow relatively minor trauma. It is present to a degree in all instances of organic arterial occlusion due to thrombosis or embolism and occurs occasionally in association with acute thrombophlebitis.

Arteriospasm may persist in a chronic form and be associated eventually with Sudeck's atrophy, a demineralization of the bone secondary to vasospasm.

*Etiology.*—The exact mechanism of development is not known, but acute arteriospasm is undoubtedly due to reflex sympathetic action. Trauma to the vessels themselves is not essential, since injury to skeletal or nearby soft tissue structures may produce profound vasospastic effects.

*Pathology.*—In the walls of the involved vessels, there are no pathological changes due to arteriospasm *per se*. Thrombosis may occur within the lumina of the vessels if the vasospasm persists over a prolonged period of time.

*Clinical.*—The symptoms and signs of acute arteriospasm are similar to those of an acute or subacute organic arterial occlusion. The extent and the degree of the findings depend on the size and location of the involved vessels. When large arteries are involved, the clinical picture may be identical with that of sudden organic arterial occlusion. Unless the major vessel is explored, it is often difficult or impossible to determine whether there is an intravascular clot. Delayed recognition is not usually difficult if the spasm subsides.

Reflex vasospasm is of great importance in connection with organic occlusion of a major artery, since the spasm may involve not only the segment of the artery which is occluded, but also the entire vessel, the arterial tree served by the major vessel, the collateral circulatory channels, or the major vessels of the entire limb. Recognition of the factor of spasm is of vital importance since it may often be relieved by measures

or else is actually decreased. The pain of peripheral neuritis is not usually accompanied by rubor or by an elevation of skin temperature.

*Treatment.*—The treatment of erythermalgia is not uniformly successful. When it is secondary to some other condition, usually a vascular disease, an organic neurological disease, or heavy metal poisoning, treatment of the underlying condition is essential to successful management of the erythermalgia. Acetylsalicylic acid in doses as small as 10 grains (0.65 gms.) may bring about a surprising degree of relief for several days. Injections of epinephrine hydrochloride have also been reported as successful.

Some symptomatic relief may be obtained by avoiding the circumstances that cause vasodilatation. The patient may obtain relief by moving to a climate where temperatures are moderate. The patient should avoid exposing his feet to excessive warmth; he should not, for example, wear heavy socks or sit near an open fire, a stove, or a heater. The wearing of light weight socks or stockings and sandals or perforated shoes may be helpful. Treatment with roentgen rays or radium may also prove helpful but should be carried out only by an expert roentgenologist.

If these measures fail, it may very rarely be necessary to anesthetize the skin of the feet by cutting or crushing the peripheral nerves distributed to the involved areas. A logical method of treatment is the desensitization of the skin to warmth by immersing the extremities in water at 75° F. (23.8° C.) for 15 minutes twice daily for two or three days and then increasing the temperature of the water 1 or 2° for each two days of therapy. When distress is experienced, the temperature of the water should be reduced by several degrees for the subsequent treatment. There is no real evidence that this therapy is consistently helpful. Since it is sometimes impossible to be certain that peripheral neuritis may not be complicating the picture, large doses of Vitamin $B_1$ or Vitamin B complex are frequently administered.

*Prognosis.*—Complete recovery is unusual. Where the erythermalgia is secondary, the ultimate outcome depends on the primary disease.

## SYNDROMES PRODUCED BY CHANGES IN THE ENVIRONMENTAL TEMPERATURE

There are several well-defined syndromes other than Raynaud's syndrome in which changes in the environmental temperature cause signs and symptoms referable to the peripheral vascular system. Each of these syndromes is initiated by an abnormal reaction of the peripheral blood vessels to changes in environmental temperature, usually in the direction of excessive cold. The mechanisms producing the conditions are similar, but the manifestations are sufficiently different to warrant their separation into clinical entities.

Conditions which Result from Exposure to Marked Increases or Decreases in Environmental Temperatures

I. Sensitivity to cold and heat
II. Pernio
  A. Acute pernio (Acute chilblains)
  B. Chronic pernio (Chronic chilblains, erythrocyanosis)
III. Trench foot and immersion foot
IV. Frostbite

## SENSITIVITY TO COLD AND HEAT

Sensitivity to cold differs in its manifestations from chilblains and frostbite in that there is a systemic as well as a local reaction. The local lesion, occurring on the exposed portions of the body and less often on the mucous membranes as well, is typically urticarial and in severe cases may become angioneurotic edema. The systemic reaction is a typical vasovagal attack similar to that produced by the parenteral injection of histamine. The pulse rate is accelerated and the blood pressure falls; in severe attacks this results in syncope. Attacks are apt to be particularly severe if the cold sensitive patient has been exposed to an elevated temperature just before exposure to extreme cold.

The diagnosis of true sensitivity to cold can be confirmed in the office or clinic by

*Pathology*.—Information on pathology of erythermalgia is scanty. No consistent organic change has been reported.

*Physiology*.—The increased temperature of the involved skin is a constant finding. Distress appears regularly when the skin temperature is elevated above a critical point (ordinarily between 89.6 and 96.8° F. or 32 and 36° C.) and disappears when the temperature falls below that point.

Vasodilatation is the immediate cause of the increased temperature and the distress, but it is not the primary cause since distress can be produced by warming the skin to the critical temperature while the circulation has been brought to a halt by application of a tourniquet. Other manifestations of vasodilatation are increased amplitude of arterial pulsations, a subjective sense of throbbing, increased heat elimination, and increased oxygen content of the venous blood from the involved extremity. Hydrostatic pressure, though not alone the cause of the distress, does however play a role here since distress may be produced by increasing the intravascular pressure in a limb warmed to below the critical temperature and may be relieved by elevating a limb warmed to above the critical temperature. Pain may sometimes be relieved by direct pressure on the skin. It is apparent that the skin in erythermalgia is unusually sensitive to a degree of warmth tolerated with perfect comfort by the normal subject.

*Clinical*.—The usual complaint is of a burning distress in one or more extremities for a period of years. The hands and feet or localized portions of the extremities are usually involved. There is a relation between the distress and the circumstances in which the temperature of the skin is elevated (exercise, the wearing of heavy clothes, exposure to heat, *etc.*). Distress is often worse during the warm seasons. It is made worse by dependency and by elevation of the venous pressure.

The burning sensation persists for minutes or hours, but the patient may have learned that it can be relieved by exposing the involved areas to cold air or immersing them in cold water. Frequently he has learned to sleep with his feet uncovered, even in the winter.

If the patient has examined the involved area carefully, he will have noted that it becomes red or cyanotic and warm or hot to the touch during an attack. There may be a slight swelling of the area or even the whole limb, but trophic changes, gangrene, and ulcers do not occur in the primary form of the condition. When they do occur (in the condition's secondary form), they are caused by the underlying disease.

*Diagnosis*.—The diagnosis of erythermalgia is established when painful rubor is accompanied by an increased temperature of the involved skin. Distress, color changes, and elevated skin temperature occur when the limb, or the body, is warmed, or the involved limb is allowed to hang free. They are relieved by cooling the limb or elevating it. Examination of the involved areas during an attack is imperative for diagnosis. The skin temperature of that area is warmer than the corresponding area on the opposite limb. The arterial blood supply should be examined carefully by palpation of the arteries, by the elevation and dependency test, and by oscillometry. The systemic examination is important to rule out primary systemic disease.

Primary erythermalgia ordinarily involves both lower extremities and, rarely, the upper extremities as well. Secondary erythermalgia often involves only a single extremity. The diagnosis of the primary erythermalgia can be established only insofar as careful examination has failed to reveal an underlying cause.

*Laboratory*.—Temperature studies are invaluable in demonstrating the parallel relation between the increase in the skin temperature and the occurrence of rubor and distress. These studies should include demonstration that the distress is increased by dependency or increased venous pressure and relieved by elevation of the involved extremity. The blood should be examined carefully to rule out polycythemia vera.

*Differential Diagnosis*.—Primary erythermalgia must be differentiated from the occlusive arterial diseases, arteriosclerosis obliterans and thromboangiitis obliterans, in which paresthesias, burning pain, and rubor may occur. In these conditions, however, the temperature of the limb remains normal

or else is actually decreased. The pain of peripheral neuritis is not usually accompanied by rubor or by an elevation of skin temperature.

*Treatment.*—The treatment of erythermalgia is not uniformly successful. When it is secondary to some other condition, usually a vascular disease, an organic neurological disease or heavy metal poisoning, treatment of the underlying condition is essential to successful management of the erythermalgia. Acetylsalicylic acid in doses as small as 10 grains (0.65 gms.) may bring about a surprising degree of relief for several days. Injections of epinephrine hydrochloride have also been reported as successful.

Some symptomatic relief may be obtained by avoiding the circumstances that cause vasodilatation. The patient may obtain relief by moving to a climate where temperatures are moderate. The patient should avoid exposing his feet to excessive warmth; he should not, for example, wear heavy socks or sit near an open fire, a stove or a heater. The wearing of light weight socks or stockings and sandals or perforated shoes may be helpful. Treatment with roentgen rays or radium may also prove helpful but should be carried out only by an expert roentgenologist.

If these measures fail it may very rarely be necessary to anesthetize the skin of the feet by cutting or crushing the peripheral nerves distributed to the involved areas. A logical method of treatment is the desensitization of the skin to warmth by immersing the extremities in water at 75° F. (23.8° C.) for 15 minutes twice daily for two or three days and then increasing the temperature of the water 1 or 2° for each two days of therapy. When distress is experienced the temperature of the water should be reduced by several degrees for the subsequent treatment. There is no real evidence that this therapy is consistently helpful. Since it is sometimes impossible to be certain that peripheral neuritis may not be complicating the picture, large doses of Vitamin $B_1$ or Vitamin B complex are frequently administered.

*Prognosis.*—Complete recovery is unusual. Where the erythermalgia is secondary, the ultimate outcome depends on the primary disease.

## SYNDROMES PRODUCED BY CHANGES IN THE ENVIRONMENTAL TEMPERATURE

There are several well-defined syndromes other than Raynaud's syndrome in which changes in the environmental temperature cause signs and symptoms referable to the peripheral vascular system. Each of these syndromes is initiated by an abnormal reaction of the peripheral blood vessels to changes in environmental temperature, usually in the direction of excessive cold. The mechanisms producing the conditions are similar, but the manifestations are sufficiently different to warrant their separation into clinical entities.

CONDITIONS WHICH RESULT FROM EXPOSURE TO MARKED INCREASES OR DECREASES IN ENVIRONMENTAL TEMPERATURES

I. Sensitivity to cold and heat
II. Pernio
  A. Acute pernio (Acute chilblain.)
  B. Chronic pernio (Chronic chilblains, erythrocyanosis.)
III. Trench foot and immersion foot
IV. Frostbite

## SENSITIVITY TO COLD AND HEAT

Sensitivity to cold differs in its manifestations from chilblains and frostbite in that there is a systemic as well as a local reaction. The local lesion, occurring on the exposed portions of the body and less often on the mucous membranes as well, is typically urticarial and in severe cases may become angioneurotic edema. The systemic reaction is a typical vasovagal attack similar to that produced by the parenteral injection of histamine. The pulse rate is accelerated and the blood pressure falls; in severe attacks this results in syncope. Attacks are apt to be particularly severe if the cold-sensitive patient has been exposed to an elevated temperature just before exposure to extreme cold.

The diagnosis of true sensitivity to cold can be confirmed in the office or clinic by

strapping an ice cube to the patient's forearm. An urticarial reaction will develop in 10 or 20 minutes. In patients insensitive to this test, a more violent reaction may be evoked by immersing the hand and arm into a container of water maintained at a temperature of from 12 to 14° C. (53.6° to 57.2° F.) or lower. The forearm test should always be tried before the immersion test, for, in extremely cold-sensitive patients, such exposure may produce syncopal attacks. Syncope, which in some cases, is believed to have caused drowning, has resulted from immersion of the entire body in cold water.

Some persons are similarly sensitive to heat; occasionally, a person is extremely sensitive to both heat and cold. Exercise, fever, or exposure to an excessively warm environment may induce attacks identical to those induced by exposure to cold. In such instances, exposure to a cool environment immediately before exposure to heat may aggravate the attacks.

*Treatment.*—Treatment of sensitivity to heat and cold is not satisfactory. Desensitization can sometimes be accomplished by daily exposing the hand to cold water. The temperature of the water should be lowered one degree each day. Histamine injected subcutaneously in progressively larger doses has also been used with occasional success. The value of antihistaminic drugs is being studied at present. Patients sensitive to cold should be warned against swimming in cold water, taking very cold showers, or indulging in cold foods or drinks.

## ACUTE AND CHRONIC PERNIO

### (Acute and Chronic Chilblains)

In acute pernio (acute chilblains) the patient complains of an itching, burning sensation of an exposed portion of the body, usually the hands or the feet, but occasionally the nose, the cheeks or the ears. The discomfort begins during exposure to cold but is aggravated by subsequent exposure to a warm environment or by bathing in warm water. The skin becomes somewhat red, oft-times mildly cyanotic, and there is usually slight edema in the involved areas. Small blebs may appear, but there is no severe urticarial reaction as in cold sensitivity. Resolution of the reaction is slow even if there is no further exposure to cold. Purpura often occurs; occasionally, a dermatitis. Brown pigmentation may remain permanently.

Repeated exposures to cold and dampness may result in chronic pernio (chronic chilblains). When this is the case, multiple small nodules may appear over the involved areas during the early weeks of the cold season. These nodules break down over the course of several weeks and become exquisitely painful ulcers, which persist through the cold season. The ulcers heal during late spring or early summer and leave permanently pigmented marks and disfiguring scars ranging in size from a pinhead to several centimeters in diameter. In advanced cases of chronic pernio the ulcers may not heal and may become disabling.

The normal skin temperatures of many persons who develop pernio is lower than the average person's. Their extremities are cold and frequently cyanotic. There may be unexplained mild ankle edema, and livedo reticularis is sometimes present.

The pathological picture in advanced chronic pernio is characteristic though not specific. There is angiitis with intimal proliferation, thickening of the arterial wall and perivascular infiltration, necrosis of the panniculus adiposus and a chronic inflammatory reaction of the subcutaneous tissues in which giant cells appear. The lesions, nodules, blebs, and superficial and deep ulcers may be present at the same time, and purpura and hyperpigmentation are not uncommon.

Chronic pernio must be differentiated from erythema induratum, erythema nodosum and nodular vasculitis.

*Treatment.*—There is no specific treatment for pernio. The patient must be protected against cold and dampness and after exposure to cold should not be exposed to heat greater than 85° F. Trauma to the skin should be avoided. Persons with acute attacks of chilblains should not have the exposed portion of their bodies rubbed with snow. Nor should strong antiseptics be applied to the involved areas. Mecholyl iontophoresis and intravenous typhoid vaccine have been used in chronic pernio but

with only moderate success Lumbar sympathectomy gives good immediate results but is disappointing as far as long range results are concerned The sympatholytic drugs are possibly worth a trial in the treatment of pernio

## TRENCH FOOT AND IMMERSION FOOT

Trench foot results from changes in the peripheral circulation and the tissues produced by exposure to cold and *dampness* There is ordinarily, a sterile mild inflammatory reaction, often there is a history of trauma Trench foot has been observed in all battles fought in severe, wet winter weather immersion foot is a product of modern amphibious warfare

*Etiology* —The following are the etiological factors (1) prolonged immobility of the legs (2) prolonged dependency of the legs (3) cold and dampness or prolonged soaking (4) want of opportunity to remove shoes or boots and socks, for long periods (5) constriction of the legs by boots or wearing apparel (6) improper nutrition (Protein and Vitamin B deficiencies are thought to be especially important)

*Pathology* —Trench foot is characterized by thrombosis of the vessels The soft tissues and bones of the affected part become necrotic there is intense scarring and fibrosis the subcutaneous fat is atrophic and phagocytized the muscles show atrophy much like that of Volkmann s contracture and the bones show a condition resembling Sudeck s atrophy Pathologically there is a close resemblance to frostbite

The earlier changes in immersion foot have not been well described but they appear to be similar to those in mild frostbite Later changes are often associated with gangrene or secondary infection Intimal thickening and medial fibrosis occur with some perivascular reaction Thrombosis however is not prominent The skeletal tissues atrophy and the the nerves especially toward the terminations show marked degeneration

*Clinical* —The patient with trench foot develops sensations of coldness dampness numbness and woodiness There is little or no pain while he remains exposed to cold Warmth however causes marked edema subcutaneous hemorrhages marked hyperemia and intense burning pain Gangrene may follow and though apt to be superficial is often very extensive Secondary infection is a constant risk until healing is complete

The clinical picture in immersion foot consists of three phases (1) the initial, or spastic ischemic phase, (2) the postimmersion or hyperemic phase and (3) the late vasospastic or secondary ischemic phase During immersion there is both direct and reflex vasoconstriction the feet are cold pale and cyanotic and the peripheral pulses are reduced or absent Edema appears as a result of dependency and aggravates the disturbances in the circulation Petechiae and shallow ulcers may appear Anesthesia is prominent

When the patient is placed in a warm environment the feet become swollen red and hot and the pulses begin bounding Swelling progresses and hemorrhagic blebs or ulcers and gangrene may appear Anesthesia and numbness may persist for a time but are eventually followed by intense and progressive burning paresthesias This phase may persist for weeks

In severe cases after weeks or months the feet become cold and cyanotic and pain stiffness and paresthesia are present Hyperhidrosis may then appear The late manifestations of the syndrome may reappear during cold weather for some years and prove incapacitating

## FROSTBITE

In frostbite severe and prolonged vasoconstriction causes ischemia of the tissues Thromboses in the smaller arteries contribute to the tissue damage Freezing of the tissue fluids occurs and intracellular fluids crystallize and rupture the cell membranes

The true freezing point of the skin is between −2 and 0° C (28 4 and 32° F) but freezing does not occur normally at this level because of the phenomenon of supercooling Freezing of the skin often occurs between −4 and −10° C (24 8 and 14° F) but occasionally it does not occur until the temperature has fallen to −20°

C. (−4° F.), or below. Freezing is encouraged by dampness, wind, circulatory stasis and anoxemia. Peripheral vascular disease, either vasospastic or occlusive, predisposes the skin to frostbite.

Frostbite may be classified, like burns, according to degree of severity. In first-degree frostbite, the outer layers of the skin are *involved in a white or yellow lesion* accompanied by numbness or paresthesia. Blistering or peeling does not occur. The application of mild warmth causes the normal color to return, but the affected part remains hypersensitive to cold for some time.

*In second-degree frostbite there is* blistering or peeling of the superficial layers of the skin, but the deeper layers of the skin and the subcutaneous tissues are undamaged. The tissues become firm and stiff.

When thawing occurs, reactive hyperemia spreads from the periphery to the center of the *involved area and a sensation of burning* pain is commonly experienced. Edema appears and is followed by blistering. Later the superficial skin peels, the result looks like necrosis or gangrene, but the subcutaneous tissues are normal.

Third- and fourth-degree frostbite are *analogous to third- and fourth-degree burns*, the former destroys the entire thickness of the skin, the latter involves the subcutaneous and deeper tissues. Necrosis and gangrene may lead to the loss of fingers or toes or of a hand or foot.

Persons who have been frostbitten are frequently hypersensitive to further exposure to extreme or even moderate cold and may be incapacitated upon such exposure.

*Treatment. — Prophylaxis.* —Persons exposed to severe cold *should wear loose*, light, warm, multilayered clothing. Outer clothes should be windproof. The feet *should be* kept oiled and dry and lesions of any sort treated carefully. Eskimo mukluk boots or at least loose, soft boots should be worn over two pairs of wool socks. Two pairs of gloves should be worn. Care must be taken to avoid unnecessary constriction of the extremities. Standing still for long periods is *undesirable when exposed to* extreme cold.

*Active Treatment.* — Mild (first-degree) *frostbite is best treated by* applying the warmth of the hand to the involved area. Heat above body temperature is unnecessary and undesirable.

In more severe degrees of frostbite, the patient should be kept in an environment maintained at "room temperature." The *skin must not be traumatized by* rubbing with snow or by walking. Warm drinks and alcoholic drinks will promote the peripheral circulation. The temperature of the frostbitten part should be raised to normal gradually. If severe pain occurs during the warming, the frostbitten parts may be kept *cool by means of an electric fan.* The rapid development of edema also indicates too rapid a rise in temperature. Sympathetic paravertebral blocks and sympathectomy have not proved of distinct value in the treatment of frostbite. The experimental and clinical studies by Lange and Boyd *suggest that all severely frostbitten patients* should receive heparin to minimize the development of thromboses in the small vessels involved. It is important that this be administered at the earliest possible time. Recent experience with frostbite incurred in the Korean war suggests that intravenous *infusions with procaine may be the* immediate treatment of choice. Surgical treatment of gangrenous and necrotic tissues should be delayed until all possible improvement has occurred, since the amount of devitalized tissue is often less than anticipated from the external appearance of the lesions.

## NEUROVASCULAR SYNDROMES OF THE SHOULDER GIRDLE

*Several types of anatomic derangements* of the shoulder girdle may be responsible for such neurovascular syndromes involving the arms as cervical rib syndrome, scalenus-anticus syndrome, costoclavicular syndrome and hyperabduction syndrome.

*Cervical-Rib and Scalenus Anticus Syndromes.* —The cervical rib syndrome occurs in the presence of extensions of the transverse processes of the 6th or 7th (occasionally of the 5th) cervical vertebra. Usually a supernumerary rib is present, but not always; it may be represented by a fibrous or

cartilaginous band The pressure of this structure on the subclavian artery and brachial plexus leads to coldness paresthesias, impaired circulation and occasionally gangrene of the fingers

The scalenus anticus muscle may produce a neurovascular syndrome by pressing the subclavian artery against the lower and middle trunks of the brachial plexus as they lie on a cervical rib Pinching may also occur between the anterior and the medial and minimal scalene muscles above their points of attachment to the first rib

Section of the scalenus-anticus muscle usually affords relief if the symptoms arise from the pinching of nerves and vessels between the first rib and the clavicle In the presence of a cervical rib such section is not so likely to afford relief

*Costoclavicular Syndrome* —In some persons holding the shoulders back and down or hyperextension of the neck pinches the vessels and the brachial plexus between the anterior surface of the first rib and the posterior surface of the clavicle Obliteration of the pulse may result Usually however unusual activity such as carrying a heavy pack is required to produce the syndrome Relief may be obtained by exercises that strengthen the shoulder muscles It is occasionally necessary to remove a rib or a section of a rib or to groove one of the ribs

*Hyperabduction Syndrome* —The hyperabduction syndrome is characterized by paresthesias numbness and tingling in the arms on holding them over the head for long periods of time It occurs most commonly in persons who sleep with the arms in hyperabduction and with the elbows flexed

Movement during sleep ordinarily relieves the discomfort Occasionally tingling loss of sensation swelling desquamation causalgia and even gangrene of the fingers may occur The syndrome is commonly seen as an occupational condition among aircraft workers painters and garage mechanics

## THE OCCLUSIVE ARTERIAL DISEASES

The occlusive arterial diseases are organic obliterative and obstructive conditions differing in etiology whose common denominator is eventual partial or complete arterial occlusion Occlusion may be insidious and slowly progressive as in uncomplicated arteriosclerosis obliterans or thromboangiitis obliterans or sudden and acute as in sudden arterial occlusion from thrombosis or embolism

**CLASSIFICATION OF THE OCCLUSIVE ARTERIAL DISEASES**

A Arteriosclerosis
  1 Generalized arteriosclerosis
  2 Arteriosclerosis obliterans
  3 Medial (Monckeberg's) arteriosclerosis
B Thromboangiitis obliterans (Buerger's disease)
C Simple arterial thrombosis
  1 Associated with infectious diseases
  2 Associated with blood dyscrasias
  3 Secondary to trauma or compression
  4 Idiopathic
D Arterial embolism
  1 Commonly from a thrombus (blood clot)
  2 Uncommonly bacterial neoplastic, fungus inorganic substances fat or air

## ARTERIOSCLEROSIS

### (Atheromatosis Atherosclerosis)

Arteriosclerosis is a degenerative process involving primarily the intima and sometimes the media of the walls of the arteries It is usually detectable during early or middle adult life and progresses insidiously Arteriosclerosis in the predominately elastic arteries the aorta and its branches is confined almost exclusively to the intima which becomes thickened and distorted as a result of the deposition of lipoid materials These deposits may become calcified or necrotic In severe cases the muscle fibers of the media may atrophy and be replaced with fibrous tissue Arteriosclerosis of the predominately muscular arteries the arterial trunks leading out into the extremities may involve the media without significant intimal change This is called Monckeberg's sclerosis

The term *atheromatosis* (atherosis) applies to the early stage of arteriosclerosis In this stage the lesions are relatively small isolated fatty subintimal plaques known as atheromata The term *atherosclerosis* is commonly applied to advanced degrees of atheromatosis When the arterioles are

involved, one speaks of *arteriolar sclerosis*

*Etiology*.—The etiology of arteriosclerosis is not known. Many theories have been advanced but only two warrant discussion here.

*Mechanical Theory*.—Since the time of Virchow, arteriosclerosis has been explained as a result of continuous trauma to the walls of the arteries due to the pulsating pressure of the circulating blood. The evidence is as follows:

1) Arteriosclerosis is generally associated with age but is clearly not related directly to age alone. Some persons have advanced lesions during the fourth decade of life or even earlier; others have no significant arteriosclerosis even at an advanced age. Both extremes, however, are exceptions to the rule. The earliest manifestations are ordinarily found in comparatively young adults, and the lesions tend to increase in size, number and extent as the years pass; the severest lesions are most frequently seen in persons of advanced age.

2) Severe degrees of arteriosclerosis often appear in several members of a single family and involve most extensively vessels of the same organ. This suggests that heredity may predispose to arteriosclerosis.

3) Although arteriosclerosis involves all parts of the vascular system, it commonly attacks arteries of a certain size, histological character and location—usually the elastic arteries, the aorta and its branches, the cerebral and the coronary arteries and the arterial trunks supplying the extremities.

4) Within the arteries most severely involved certain sites are usually especially affected. When the arteriosclerotic process is young, atheromata tend to develop in areas of maximum trauma: in the posterior wall of the aorta, in the site of insertion of the ductus arteriosus, in the bifurcation of the iliac arteries, and, if there is mitral valve disease, in the pulmonary circulation.

5) Arteriosclerosis obliterans is much more common in the lower than in the upper extremities. This is in keeping with the fact that arterial blood pressure is somewhat greater in the lower than in the upper extremities. The lower extremities are also subjected to more stress in most individuals.

6) Arteriosclerosis tends to develop earlier in life and to be more severe in patients with hypertension.

7) Atheromata are commonly found clustered around the mouths of the intercostal and other branches of the aorta and in similar locations where the stresses on the vessel walls are greater than elsewhere.

According to the mechanical theory, atheromata must be considered the result of a degenerative process in which lipoids are deposited secondarily and in a manner not necessarily related to any disturbance of lipoid metabolism.

*Metabolic Theory*.—Whether arteriosclerosis develops as a sequel to disturbed *cholesterol and lipid metabolism* within the organism is currently the subject of intensive experimental and clinical investigation. Here again the evidence is very convincing but we are plagued by a totally inadequate knowledge of the metabolism of the lipids. The evidence for this theory follows:

1) Atheromata of all ages and sizes contain large quantities of lipids in proportions similar to those found in the circulating plasma. This suggests that the deposits may result from nonselective infiltration from plasma to intima.

2) Lesions similar to the atherosclerotic lesions in man have been produced repeatedly and by numerous investigators in rabbits by the feeding of cholesterol or animal fat. What differences there are may be explained on the basis of species differences. Rabbits do not metabolize fats or cholesterol efficiently and when fed these substances develop marked hypercholesterolemia. Similar feeding experiments with other animals have failed to produce either hypercholesterolemia or arteriosclerotic lesions except when hypothyroidism has been produced by thiouracil.

3) Various disturbances of lipid metabolism in man which are accompanied by lipemia are frequently associated with severe atherosclerosis. Examples include idiopathic lipemia, xanthomatosis, diabetes mellitus and myxedema. Atherosclerosis was extremely common among diabetics during the pre-insulin era when high fat diets were commonly used in the treatment of diabetes mellitus. Atherosclerosis was

not common in Germany after World War I, when diets were comparatively low in fat

4) The levels of the plasma lipids including cholesterol cholesterol esters phospholipids and fatty acids appear to be elevated in many arteriosclerotics but owing to the variety of methods used in determining these substances in the blood to the considerable overlapping of the values obtained and to the great variation in the results as reported it is difficult to draw conclusions from the published data

5) One explanation of the deposition of cholesterol in the form of atheromatous plaques is that it passes from the blood plasma by direct filtration through the endothelium into the subendothelial tissues According to this view when the colloidal equilibrium of the plasma is disturbed inert cholesterol is able to diffuse into the subendothelial tissues It is engulfed by macrophages to produce the characteristic lipophages or cells engorged with fat Hueper has produced atherosis in animals by the intravenous injection of polyvinyl alcohol methyl cellulose pectin and acacia The lesions are histologically similar to those of atherosis in man and the localization is similar to that of cholesterol atherosis

6) The lipids in some persons blood are unusual in that the particles in suspension are particularly large visible by darkfield microscopy and separable by ultracentrifugation The size of the particles is not correlated with the absolute value of cholesterol in the blood Similar large particles have been observed in the plasmas of experimental animals after the administration of the substances used by Hueper to produce atherosis

Atherosclerosis may occur in persons predisposed to atherosis by the presence consistently or postprandially, of relatively large aggregates of lipoprotein components in the plasma By analytical ultracentrifugation Gofman has found four chief classes of lipoprotein components in sera

The class Sf10-20 was significantly elevated in patients with angina pectoris myocardial infarction nephrosis and in the majority of patients with hypothyroidism It appears that the type of lipoid material in the blood or the size of the chylomicrons may be more important than the actual amount of circulating lipids in the blood

7) Leary has explained atherosclerosis as follows Cholesterol is esterified in the liver by hepatic parenchymal cells During periods of overloading the lipid material accumulates in the parenchyma of the liver and damages the hepatic cells

These damaged cells are phagocytized by reticuloendothelial cells within the liver, which then become lipophages The lipophages enter the hepatic sinusoids and pass into the systemic circulation They adhere to the endothelium enter the subendothelial spaces and produce atheromata

To explain the localization of the atheromata Leary argues that the fibroblasts in the walls of the vessels are ordinarily able to remove cholesterol and that this ability is lost in certain vessels during adult life Gordon has carried this explanation a step further He states that the lipophages are less dense than other formed elements in the blood They move to the periphery of the moving blood stream and are forced against the endothelium by arterial pressure They enter the intima but are prevented from migrating beyond the internal elastic membrane which is impermeable to them In support of his view he points out that atheromata occur mainly in elastic arteries where the current is stronger and more intermittent than it is peripherally

8) Females tend to develop arteriosclerosis from five to ten years later than males which suggests that hormonal or metabolic differences may play some part in the development of the condition

## Pathology

The atheromatous process in early life consists of the development of the small intimal fatty plaques which arise from the deposition of cholesterol esters in the intercellular cement deep in the intima These plaques enlarge coalesce and gradually involve more superficial layers of the *intima* The process finally involves the surface endothelium and is visible in the lumen

True atherosclerosis usually appears in persons over 45 but varies widely in extent severity and localization Not only is fat

Fig 173 —Arteriosclerosis Hyaline degeneration involving entire thickness of wall of arterioles × 150 (Boyd Pathology of Internal Disease)

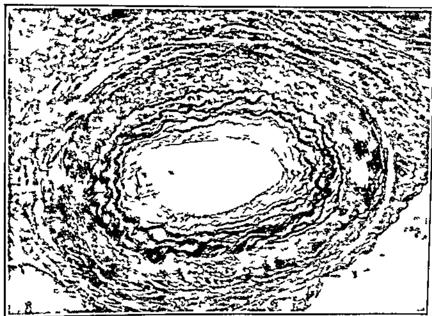

Fig 174 —Elastosis There is marked uniform thickening of the intima with reduplication of the internal elastic lamina From a case of essential hypertension (Elastic ti ue stain) × 150 (Boyd Pathology of Internal Disease)

laid down in the intercellular spaces of the intima but there is a fibrous reaction about it

Proliferation of the connective tissue elements in the intima is followed by hyaline degeneration, which produces the sclerotic intimal plaque In a given individual plaques of all sizes and degrees of development may be seen some of them simple atheromata others advanced atherosclerotic plaques Advanced lesions may become completely calcified or undergo necrosis and ulceration

### Pathological Physiology

Advanced arteriosclerosis may exist without clinical evidence of disease Symptoms arise as a result of impaired circulation and depend as much upon the location of the lesions as upon their number or stage of development In the smaller arteries the intimal thickening resulting from the atherosclerotic process and the secondary vasospasm may produce obstruction and occlusion In the larger arteries thrombosis produces occlusion

The importance of arteriosclerosis depends largely on its localization in terms of the organs involved Advanced arteriosclerosis is accompanied by atrophy of the capillary bed and subsequently by atrophy of the parenchyma of the organ involved

The high blood pressure accompanying advanced arteriosclerosis differs from that of essential hypertension in that only the systolic blood pressure is elevated

### Clinical Signs

In general the manifestations of arteriosclerosis are those described as senile changes—atrophy of the skin and its supporting tissues mental and physical impairment loss of memory for recent events increased irritability intolerance to cold and heat diminished resistance to infection delayed healing of wounds and predisposition to fractures (which heal slowly or not at all)

The localized clinical manifestations of arteriosclerosis are referable to the organ involved Cerebral arteriosclerosis may be manifested by the general signs of senility or by focal phenomena arising from involvement of major arteries Thrombosis aneurysm and hemorrhage complicate the arteriosclerotic process The results are ischemia from pressure and obstruction or infarction from complete occlusion In the end the brain substance degenerates and softens

Arteriosclerosis of the coronary arteries produces angina pectoris coronary insufficiency or coronary occlusion with myocardial infarction the last is commonly associated with thrombosis of a major coronary artery Myocardial failure with or without congestion is the result in patients who do not succumb to vascular occlusions or intercurrent diseases

Arteriosclerosis of the kidneys results in small contracted senile kidneys in which the circulation is impaired generally The clinical manifestations are polyuria nocturia and inability to concentrate the urine Edema does not develop but there is progressive impairment of renal function leading eventually, to uremia

### Diagnosis

The diagnosis of arteriosclerosis depends on the recognition of the stigmata of aging and on identification of the process as the cause of focal symptoms and signs occurring in the various vital organs Simple and readily performed bedside procedures are palpation of the peripheral arteries (the physician should remember to palpate the arteries of the feet) and examination of the fundi with the ophthalmoscope Roentgen examination of the major vessels may disclose the increased tortuosity characteristic of the disease and the deposition of calcium in the walls of the vessels Oscillometric readings of the extremities will indicate closure of or unusual lack of pulsation or elasticity in the major arteries but the cause must then be determined

### Laboratory Findings

In addition to the roentgen examination of the major vessels a variety of simple laboratory procedures are useful in making the diagnosis and determining the extent of the involvement of arteriosclerosis The

Fig 173 —Arteriosclerosis Hyaline degeneration involving entire thickness of wall of arterioles × 150 (Boyd Pathology of Internal Disease)

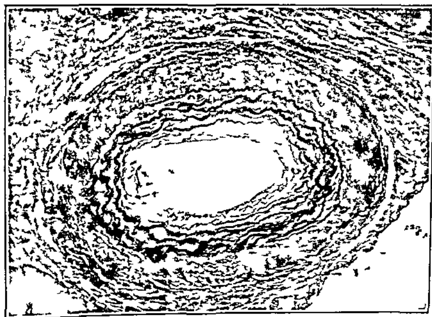

Fig 174 —Elastosis There is marked uniform thickening of the intima with reduplication of the internal elastic lamina From a case of essential hypertension (Elastic tissue stain) × 150 (Boyd Pathology of Internal Disease)

been necrosis or ulceration of the intima In the presence of such blood dyscrasias as hemophilia, thrombophilia and polycythemia thrombosis is likely to occur early in the development of atherosclerosis Postoperative and post traumatic thrombosis is very apt to occur in patients with atherosclerosis Any infectious disease or period of debility may be complicated by intravascular clotting in these patients

## INCIDENCE

Arteriosclerosis obliterans occurs predominantely in males over fifty

It is particularly likely to occur in patients with diabetes mellitus There is no definite evidence that it occurs with any greater severity among hypertensive persons than among others

sclerotic process is advanced the vessels may not be able to dilate significantly

The atheromatous plaques in the walls of the arteries project into the lumen as they enlarge adjacent plaques coalesce to form increasingly larger bodies Fibrous tissue is laid down around the plaques and the focal areas become calcified or necrotic Areas of degeneration may produce ragged, necrotic ulcers over which thrombi tend to form

The degree of involvement varies from vessel to vessel Progressive fibrosis of the intima results in an irregular thickening that reduces the diameter of the lumen Fibrosis progresses to involve both the media and the adventitia Calcification in the deeper layers of the intima may encircle the vessel completely

In the arterial trunks of the extremities

TABLE 50 —PATHOLOGICAL FEATURES WHICH DIFFERENTIATE ARTERIOSCLEROSIS OBLITERANS AND THROMBOANGIITIS OBLITERANS

| | *Arteriosclerosis Obliterans* | *Thromboangiitis Obliterans* |
|---|---|---|
| Thrombus | Irregularly deposited half moon-shaped layers of various ages Irregular and relatively acellular organization | Extensive organization containing endothelial cells and fibroblasts |
| Intima and subintima | Extensive atheromata formation usually eccentric Deposition of lipophages fat and cholesterol Often calcification | Inflammatory type of response Extensive proliferation of endothelium but no atheroma formation and consequently no deposition of fat cholesterol or calcium |
| Media | Irregular fibrosis and hyalinization often calcium deposition Thinning and appearance of moderate foci of lymphocytes and fibroblasts | Diffuse fibroblastic proliferation centering around vasa vasorum but muscular layers are preserved No calcium deposits |
| Adventitia | Irregular fibrosis Occasional foci of lymphocytes | Fibroblastic proliferation leads to periarterial fibrosis Marked endothelial proliferation of vasa vasorum |

## PATHOLOGY

Localized but widely distributed and extensive obstructive lesions involve the large and small arterial trunks When occlusion involves important arterial trunks or important collateral circulation or occurs suddenly ischemia of the tissues supplied by these vessels results The degree of ischemia may be increased by arteriolar constriction (from any cause—exposure to cold use of tobacco) or reduced as a result of vasodilatation as produced by heat or the use of vasodilator drugs If the arterio-

a distinctive type of arteriosclerosis Monckeberg s sclerosis not infrequently occurs In this condition there are degeneration and calcification of the media sometimes without significant intimal involvement The plate-like deposits tend to encircle the arteries and convert them into semi rigid tubes This process may extend from the iliac vessels down into the feet

The occurrence of hemorrhage around the vasa vasorum has been described in detail by Winternitz and others It is not clear whether such hemorrhage is primary or secondary

urinary sediment should be examined and the ability of the kidneys to concentrate urine determined The electrocardiogram is useful in assessing the status of the heart and the coronary circulation The hemoglobin concentration and erythrocyte count should be determined because of the common occurrence of secondary anemia, usually on a nutritional basis

### Treatment

There is no specific treatment of established value for the treatment of generalized arteriosclerosis The treatment of organs affected by arteriosclerosis is discussed in the chapters devoted to those organs General nonspecific measures are those which protect the patient against unnecessary strain and intercurrent disease infection particularly

*a*) Avoidance of exposure to excessive cold or heat Residence in a moderate climate is desirable when possible

*b*) Adequate but restricted diet Obesity *should be avoided weight reduction is* indicated when significant obesity exists Attention must be directed to assuring a well balanced diet, since patients of advanced age are prone to be careless about their eating habits Though some physicians advocate a low-cholesterol diet, this is so far based on inconclusive evidence *

*c*) Personal hygiene must be scrupulous The need for care in personal hygiene especially as to the feet increases as the resistance of the body is lessened yet the aged patient is often careless about such matters Instruction is not enough these patients require demonstration and supervision

*d*) Mental hygiene Mental deterioration and psychological maladjustment are common The elderly patient must be advised about his work and relaxation, his business and personal affairs He is prone to make mistakes and perform unexpected acts as a result of the gradual impairment of his memory and judgment

* According to Gofman and associates very low fat diets (50 gm ) with cholesterol restriction to 200 mg daily produce a reduction in the blood level of $S_f$ 10-20 molecules —Editor

### Prognosis

The prognosis must be guarded arteriosclerosis is inexorable and any one of a number of complications may ensue at any time—intravascular clotting hemorrhage vascular aneurysm and rupture, *etc* In general the chain of symptoms progresses gradually, regardless of the organs involved Death if not from intercurrent disease or trauma, occurs directly as the result of the arteriosclerosis It may however, occur as a result of acute coronary occlusion with myocardial infarction, myocardial weakness or congestive heart failure, renal insufficiency with uremia cerebrovascular accidents such as thrombosis, embolism and hemorrhage or the effects of acute arterial occlusion and gangrene The immediate cause of death from these complications is shock infection or toxemia Diabetes mellitus makes the prognosis considerably less favorable

## ARTERIOSCLEROSIS OBLITERANS

(Occlusive Arteriosclerosis Senile Gangrene, Diabetic Gangrene)

Arteriosclerosis obliterans commonly occurs in the extremities during the later decades of life It is characterized by progressive obliteration of the arterial lumina and frequently by episodes of acute and *complete occlusion It is the most common* of the peripheral occlusive arterial diseases and accounts for well over 50 per cent of such cases Its cause and development and the pathological picture presented are similar to those of arteriosclerosis elsewhere in the body

### Etiology

Age and the burden of living play important parts in the progress of the pathological changes in the vessels Disturbed lipid metabolism (hyperlipemia) is now known to be a potent factor in the production of atheromata

Thrombosis may occur as a complication in early or advanced arteriosclerosis The numerous (and ill understood) factors regulating intravascular clotting determine this event It occurs more readily in the presence of small atheromata when there has

heart disease renal disease or thyroid deficiency

7) *Condition of the Arteries* —Palpation of the arteries may disclose nodulation or hardening due to calcification Resistance to compression is usually most readily apparent in the radial arteries Increased tortuosity is usually visible in the brachial arteries

8) *Ulcers* —The ulcers of arteriosclerosis obliterans are due to ischemia and are commonly precipitated by trauma or by a splitting of the skin through fungus infection The ulcers tend to occur on the toes or between them on the heels and on the anterior tibial surfaces

Unless infected they tend to be dry Secondary infection by bacteria or fungi is very common The ulcers tend to extend themselves by undermining the surrounding skin margin and are not infrequently covered by a black eschar

9) *Gangrene* —Gangrene due to arteriosclerosis obliterans may involve a minute focal area or a large portion of the affected limb It depends on the size and location of the occluded vessel and on such other factors as the nutritional state of the patient the adequacy of the collateral blood supply and the occurrence of trauma and secondary infection Closure of even such major arterial trunks as the iliac arteries may not lead to gangrene if the collateral circulation is adequate Gangrene may involve a minute area and spread progressively or involve an entire digit or a large portion of an extremity (as a result of the occlusion of a major vessel for which no adequate collateral circulation exists) The pain is variable If infection does not supervene the area may remain dry and become mummified

## Special Examination

Certain tests are useful in the study of impaired peripheral arterial circulation regardless of etiology

1) *Oscillometry* —Oscillometry is valuable in determining the patency of major arteries and the level of occlusion

Oscillometry may give normal readings when major vessels are patent but subsidiary vessels at the same level are occluded it may show adequate circulation when palpation fails to do so because of the aberrant location of the major vessels Oscillometry is valuable when it discloses a distinct difference in the degree of pulsation at the same level in opposite limbs It is not of value in determining the adequacy of collateral circulation Oscillometry should always be performed in a warm room since chilling may produce vasospasm and diminished pulsations

2) *Surface temperature Studies* —The surface temperatures of two extremities may be compared clinically with satisfactory accuracy by palpation it is occasionally advisable to determine the skin temperature more accurately by means of a thermocouple For exact results this must be done in an environmental temperature that is kept constant

3) *Reflex vasodilatation Test* —To determine the potential ability of the vessels of a limb to dilate reflex vasodilatation or sympathetic block may be used The simplest test involves the application of heat to the arms or the trunk Where vasospasm is intense and unresponsive to simple measures the sympathetic nerves may be blocked by spinal anesthesia paravertebral block or local nerve block

4) *Claudication Tests* —It is helpful in assessing the degree of functional impairment and estimating improvement under therapy to have the patient climb stairs or walk a certain distance at a fixed pace

Similar and perhaps more accurate results can be obtained with an ergometer or by means of the forced contraction of the muscles through faradic stimulation (Landis) It is important in such studies to be certain that the pace of the patient is constant from test to test

## Laboratory Findings

1) *X rays* —Soft tissue roentgenograms of the leg and thigh and sometimes of the pelvis the lumbar region and the abdomen may help demonstrate calcified vessels Calcifications can be demonstrated in about two-thirds of the men and one-third of the women with arteriosclerosis obliterans Cal-

Thrombosis is the usual result of the vascular changes of arteriosclerosis obliterans It almost always occurs in advanced sclerosis and is not uncommon even in mild arteriosclerosis Thrombosis is probably related to alterations in the coagulation mechanism of the blood as well as to changes in the blood flow and to structural alterations in the walls of the vessels Organization and recanalization are ordinarily prominent in arteriosclerosis obliterans

Aneurysms of the peripheral arteries are relatively common late sequellæ of arteriosclerosis obliterans The popliteal and the innominate arteries are common sites Aneurysms may be saccular or dissecting and false aneurysms are not rare

## Clinical Signs

The signs and symptoms most commonly produced by arteriosclerosis obliterans are

1) *Pain* —Pain is the most common presenting symptom it may simulate that of arthralgia, neuritis *etc* but is most commonly that of intermittent claudication Pain at rest is common, and ischemic neuritis frequently occurs

Intermittent claudication is a syndrome caused by the relative ischemia of muscle groups upon activity It is analagous to angina pectoris It is characterized by extreme fatigue and tightness or cramping pain pain increased by walking a limited distance and relieved by resting for a short period Resumption of activity causes the pain to return

Claudication occurs most commonly in the muscles of the calf but also occurs in the muscles of the feet and thighs and occasionally in the muscles of the arms as among laborers Claudication is sometimes worse during cold weather and is aggravated by walking rapidly or up a grade of even modest degree The pain of intermittent claudication is characteristic (*a*) it is produced by exercise (*b*) it appears regularly and promptly after a given degree of exercise and (*c*) it is relieved by rest Claudication may be effected in a normal extremity by binding a tourniquet tightly around the proximal portion so as to occlude the arterial blood supply and then having the patient exercise the limb

Rest pain, which occurs while the patient is in bed, is like a cramp or dull ache It is presumably due to relative ischemia ischemia resulting from stagnation of the blood and the consequent impairment of nutrition and accumulation of metabolic wastes Severe neuritic pain may arise as a result of ischemia of the nerves

2) *Sensory Disturbances* —Patients with arteriosclerosis obliterans commonly complain of coldness numbness and tingling in the hands and feet and of difficulty in warming the extremities The surface temperatures are very often reduced even when the patient is not conscious of coldness In instances of arterial occlusion the surface temperature is usually distinctly lowered until the collateral circulation has become adequate skin temperature may remain depressed because of vasospasm Vibratory sensation may be impaired

3) *Trophic Changes* —Ischemia of the limb leads to trophic changes as a result of impaired nutrition There is atrophy of the skin and of the nails the latter becoming brittle thickened and deformed With advanced atrophy of the skin sweating is reduced and the growth of hair impaired Muscle atrophy is a prominent sign of chronically impaired peripheral circulation and produces the characteristic *pipe stem* legs of the aged

4) *Postural Color Changes* —The occurrence of extreme pallor upon the elevation of an extremity and of striking rubor often accompanied or followed by cyanosis upon dependency is definite evidence of arterial insufficiency Often pallor or rubor predominates but one is rarely present in the total absence of the other The time required for the feet to become distinctly pale upon elevation and brightly flushed upon dependency is useful in estimating the patency of the arterial supply

5) *Edema* —Since the venous pressure is not increased by arteriosclerosis obliterans edema does not occur on this basis alone If edema does exist a careful search must be made for local or systemic complication venous impairment nutritional disturbance

heart disease renal disease or thyroid deficiency

7) *Condition of the Arteries* —Palpation of the arteries may disclose nodulation or hardening due to calcification Resistance to compression is usually most readily apparent in the radial arteries Increased tortuosity is usually visible in the brachial arteries

8) *Ulcers* —The ulcers of arteriosclerosis obliterans are due to ischemia and are commonly precipitated by trauma or by a splitting of the skin through fungus infection The ulcers tend to occur on the toes or between them on the heels and on the anterior tibial surfaces

Unless infected they tend to be dry Secondary infection by bacteria or fungi is very common The ulcers tend to extend themselves by undermining the surrounding skin margin and are not infrequently covered by a black eschar

9) *Gangrene* —Gangrene due to arteriosclerosis obliterans may involve a minute focal area or a large portion of the affected limb It depends on the size and location of the occluded vessel and on such other factors as the nutritional state of the patient the adequacy of the collateral blood supply and the occurrence of trauma and secondary infection Closure of even such major arterial trunks as the iliac arteries may not lead to gangrene if the collateral circulation is adequate Gangrene may involve a minute area and spread progressively or involve an entire digit or a large portion of an extremity (as a result of the occlusion of a major vessel for which no adequate collateral circulation exists) The pain is variable If infection does not supervene the area may remain dry and become mummified

## Special Examination

5) *Edema* —Since the venous pressure is not increased by arteriosclerosis obliterans edema does not occur on this basis alone If edema does exist a careful search must be made for local or systemic complication venous impairment nutritional disturbance

### Prognosis

Arteriosclerosis obliterans is a progressive degenerative disease hence the prognosis must always be guarded Owing to the development of collateral circulation however the outlook in many cases is much better than would be supposed

Many factors play a role in determining the eventual outcome the extent of the occlusive process the speed with which it develops the stage of the disease at which treatment is started the adequacy of the collateral circulation the presence or absence of trauma the age of the patient and the presence or absence of diabetes and other complicating diseases As a rule however, the life expectancy of patients with arteriosclerosis obliterans is reduced Death usually occurs as a result of coronary occlusion cerebrovascular accident mesenteric thrombosis or bronchopneumonia The mortality rate after amputation formerly relatively high has been markedly reduced by modern surgical techniques and antibiotic and chemotherapeutic drugs

### Basic Principles of Treatment of Arteriosclerosis Obliterans

1 Protection of tissues whose blood supply has been impaired
2 Prevention of vasoconstriction and production and maintenance of vasodilatation
3 Relief of pain
4 Use of local measures to heal ulcers and limit gangrene
5 Prevention of progress of disease
6 Amputation the final resort

### Plan of Treatment Involving these Principles

I *Procedures applying to all cases*
- A Education of patient on care and protection of feet
- B Institution of low fat low-cholesterol diet in instances of hyperlipemia
- C Reduction of weight if patient is obese
- D Careful control of patients with diabetes mellitus
- E Control of polycythemia if present
- F Strict limitation of tobacco

II *Additional measures in cases with intermittent claudication only*
- A Warm bath daily (temp 95–100° F or 35–37 7° C ) followed by anointing of feet with oil or lanolin
- B Postural exercises three times daily (Buerger s exercises)
- C Use of vasodilator substances (*e g* alcoholic beverages, Priscoline* Roniacol*)
- D Sympathetic block (or sympathectomy) in certain instances
- E Use of reflex heat

III *Additional measures in cases with ischemic neuritis or rest pain but without ulcers or gangrene*
- A Hospitalization and absolute bed rest
- B Use of an oscillating bed if available
- C Maintenance of temperature of room at 80–85° F (26 6 to 29 4° C )
- D Application of reflex heat to abdomen and trunk
- E Administration of alcohol by mouth b i d or t i d
- F Prescription of analgesics as necessary for relief of pain
- G Trial of sympathetic blocking agents
- H Sympathetic lumbar block
- I Sympathectomy in selected cases

IV *Additional measures in cases with ulcers or superficial gangrene*
- A Hospitalization at absolute bed rest in a warm room
- B Use of an oscillating bed if available
- C Warm soakings with normal saline solution
- D Local application to infected ulcers or gangrene of sulphonamides or antibiotics in appropriate solution or ointment
- F Local application of powdered erythrocytes to clean healing ulcers

cification, whether localized and patchy or regularly distributed and confluent, does not prove obliteration of the lumina of the arteries but may support such a diagnosis made on clinical grounds Roentgenograms of the feet may demonstrate osteoporosis Arteriography is not often necessary it may be useful occasionally in demonstrating the extent of the process and in locating sites of obstruction when surgical intervention is contemplated

2) *Blood sugar Determination* —The common occurrence of diabetes mellitus in patients with arteriosclerosis requires that all patients with arteriosclerosis have a careful urinalysis and a blood sugar determination A glucose tolerance test is desirable occasionally

5) *Electrocardiograms* —Because of the common coexistence of coronary atherosclerosis an electrocardiogram should be obtained

## Diagnosis

To make the diagnosis of arteriosclerosis obliterans it is necessary to demonstrate objectively the presence of occlusive arterial disease This is done by demonstrating absent or grossly impaired peripheral pulses and is supported by demonstrating abnormal postural color changes typical intermittent claudication and the presence of ulcers or gangrene The age of the patient is an important consideration 95 per cent of the patients 50 or older with occlusive arterial disease have arteriosclerosis obliterans The

TABLE 51 —DIFFERENTIAL DIAGNOSIS BETWEEN ARTERIOSCLEROSIS OBLITERANS AND THROMBOANGIITIS OBLITERANS

| | *Arteriosclerosis Obliterans* | *Thromboangiitis Obliterans* |
|---|---|---|
| Age at onset of symptoms | Usually over 40 years | Usually under 50 years |
| Sex | 75% of serious cases in the male | More than 95% of cases in the male |
| Involvement of upper limbs | Rare | In less than ⅓ of cases |
| Superficial phlebitis | Absent | In somewhat less than half of cases |
| Calcification of arteries | Present in about two-thirds of patients | Absent |
| Hypertension | Present in at least a third of cases | Unusual in early years of disease |
| Diabetes mellitus | Present in one-fifth of all cases | Unusual in early years of disease |
| Plasma lipids | Hyperlipemia common | Usually normal |

3) *Plasma lipid Studies* —Hyperlipemia is exceedingly common in patients with arteriosclerosis and should be studied in instances where the diagnosis is in doubt

4) *Hematocrit Determinations* — Polycythemia is not unusual in patients with arteriosclerosis obliterans and predisposes to intravascular clotting All patients with arteriosclerosis obliterans should have a careful blood count and hematocrit determination

If it is suspected that the coagulation mechanism is disturbed the coagulation time and the prothrombin time should be studied

differential diagnosis between arteriosclerosis obliterans and thromboangiitis obliterans is often difficult in men between 40 and 50 years of age Nearly all instances of occlusive arterial disease in women are arteriosclerotic although the average age of onset of symptoms is nearly a decade later than in men X ray evidence of calcification favors though its absence does not exclude the diagnosis of arteriosclerosis obliterans Evidence of generalized arteriosclerosis or hyperlipemia also favors such a diagnosis

*Differential Diagnosis* —*See* accompanying table

### Prognosis

Arteriosclerosis obliterans is a progressive, degenerative disease; hence the prognosis must always be guarded. Owing to the development of collateral circulation, however, the outlook in many cases is much better than would be supposed.

Many factors play a role in determining the eventual outcome: the extent of the occlusive process, the speed with which it develops, the stage of the disease at which treatment is started, the adequacy of the collateral circulation, the presence or absence of trauma, the age of the patient, and the presence or absence of diabetes and other complicating diseases. As a rule, however, the life expectancy of patients with arteriosclerosis obliterans is reduced. Death usually occurs as a result of coronary occlusion, cerebrovascular accident, mesenteric thrombosis, or bronchopneumonia. The mortality rate after amputation, formerly relatively high, has been markedly reduced by modern surgical techniques and antibiotic and chemotherapeutic drugs.

### Basic Principles of Treatment of Arteriosclerosis Obliterans

1. Protection of tissues whose blood supply has been impaired.
2. Prevention of vasoconstriction and production and maintenance of vasodilatation.
3. Relief of pain.
4. Use of local measures to heal ulcers and limit gangrene.
5. Prevention of progress of disease.
6. Amputation, the final resort.

### Plan of Treatment Involving These Principles

I. *Procedures applying to all cases*
   A. Education of patient on care and protection of feet.
   B. Institution of low fat, low-cholesterol diet in instances of hyperlipemia.
   C. Reduction of weight if patient is obese.
   D. Careful control of patients with diabetes mellitus.
   E. Control of polycythemia if present.
   F. Strict limitation of tobacco.

II. *Additional measures in cases with intermittent claudication only*
   A. Warm bath daily (temp. 95–100° F or 35–37.7° C) followed by anointing of feet with oil or lanolin.
   B. Postural exercises three times daily (Buerger's exercises).
   C. Use of vasodilator substances (e.g., alcoholic beverages, Priscoline®, Roniacol®).
   D. Sympathetic block (or sympathectomy) in certain instances.
   E. Use of reflex heat.

III. *Additional measures in cases with ischemic neuritis or rest pain but without ulcers or gangrene*
   A. Hospitalization and absolute bed rest.
   B. Use of an oscillating bed if available.
   C. Maintenance of temperature of room at 80–85° F (26.6 to 29.4° C).
   D. Application of reflex heat to abdomen and trunk.
   E. Administration of alcohol by mouth b.i.d. or t.i.d.
   F. Prescription of analgesics as necessary for relief of pain.
   G. Trial of sympathetic blocking agents.
   H. Sympathetic lumbar block.
   I. Sympathectomy in selected cases.

IV. *Additional measures in cases with ulcers or superficial gangrene*
   A. Hospitalization at absolute bed rest in a warm room.
   B. Use of an oscillating bed if available.
   C. Warm soakings with normal saline solution.
   D. Local application to infected ulcers or gangrene of sulphonamides or antibiotics in appropriate solution or ointment.
   E. Local application of powdered erythrocytes to clean, healing ulcers.

F Administration of alcohol by mouth b i d or t i d
G Prescription of analgesics as necessary for relief of pain
H Use of sulphonamides or antibiotics orally or parenterally for systemic action, as indicated

V *Additional measures in cases of extensive gangrene, severe ulceration or osteomyelitis*

A Measures as in IV
B Delay in amputation, if possible until demarcation and possible slough
C Amputation at lowest possible level but with due consideration for the future use of a satisfactory prosthesis and only after patient s condition has been made optimal and infection has been controlled
D Amputation at higher level if
1 Pain is excessive or uncontrolled or
2 Gangrene is spreading

VI *Additional measures when case is complicated by an acute arterial occlusion*

A See section on treatment of acute arterial occlusion
B If circulation is reestablished follow measures under III
C If gangrene develops, use measures under IV or V

## THROMBOANGIITIS OBLITERANS
(Buerger s Disease)

Thromboangiitis obliterans is a specific inflammatory and obliterative disease of the arteries and veins It occurs almost exclusively in young men It involves the extremities (and occasionally the viscera as well) and produces ischemia of the tissues and, frequently gangrene Thromboangiitis obliterans involves all three layers of the walls of the vessels This inflammation leads to thrombosis and organization of the thrombus although it is perhaps, recanalized to a minor extent and transforms the occluded vessel into a fibrous cord

### Etiology

The etiology of thromboangiitis obliterans is not known A number of factors are known to influence both the occurrence and the course of the disease

1) *Age* —Thromboangiitis obliterans manifests itself, for the most part, in men between the ages of 21 and 45 The rare cases of thromboangiitis obliterans among children are found in those who smoke early and heavily Cases in which the condition seems first to manifest itself after the 50th year usually prove to be cases of arteriosclerosis obliterans

2) *Sex* —The disease occurs almost exclusively in men The number of reported cases among women are very few but are recently increasing This may indicate either an increase or better recognition of the disease In many of the cases among women, no pathological evidence is submitted to substantiate the diagnosis There is no satisfactory explanation for the rarity of thromboangiitis obliterans among women but there are three theories about it (*a*) that differences in the habits and exposures of the two sexes account for it (*b*) that a sex linked hereditary factor is responsible and (*c*) a biological difference provides women with immunity to the disease

3) *Race* —Thromboangiitis obliterans occurs in all racial groups so far studied It appears to be somewhat more common among Jews than among others but is not as originally thought a disease confined almost exclusively to them

4) *Heredity* —There are only isolated instances of the occurrence of the disease in two or more close relatives

5) *Occupation Trauma Cold* —Repeated studies have failed to show any relationship between the occurrence of thromboangiitis obliterans and occupation even when the occupation is arduous and involves exposure to extreme cold and dampness Trauma is often an aggravating factor and may produce a lesion which by reason of failure to heal normally may first indicate the presence of an extensive obliterative vascular disease Frostbite and fungus infections between the toes may

precipitate the initial open lesion of Buerger's disease

6) *Climate* —Cold weather has a deleterious effect on those with thromboangiitis obliterans; the disease is often first manifested with the onset of winter. Symptoms are aggravated during cold weather, which in controlled cases may cause relapses. This, however, is probably the effect of vasoconstriction superimposed upon the existing arterial insufficiency. Cases of thromboangiitis have been reported from all climates, and removal of patients with the disease from cold to warm climates does no more than relieve vasospasm.

7) *Tobacco* —The smoking of tobacco has a great deal to do with the development of thromboangiitis obliterans and with the unfavorable progression of the disease. The evidence is extensive and definite: (*a*) almost without exception patients with the disease are smokers, most of them heavy smokers. Very few authenticated cases of Buerger's disease among non-smokers have been reported. (*b*) The disease is more severe among heavy than among light smokers. (*c*) The course of the disease is significantly influenced by the patient's use of tobacco. The disease can often be arrested in the early stages solely by abstinence from tobacco. In advanced cases with ulceration or gangrene, the smoking of several cigarettes after a long period of arrest or improvement may cause a sudden dramatic aggravation of the condition. Patients with thromboangiitis who persist in smoking almost invariably do badly. Those who discontinue smoking tend to improve and may exhibit little or no progression of the disease over a period of years. (*d*) Smoking causes vasoconstriction in the peripheral blood vessels of most persons; there is slowing down of the capillary blood flow and a decided drop in the temperature of the skin of the fingertips.

The concept of vascular allergy to tobacco proposed by Harkavy *et al.*, who have reported a high incidence of hypersensitive reactions to skin tests in persons with thromboangiitis, is not widely accepted.

8) *Infection* — The inflammatory character of the vascular lesions has suggested infection by bacteria, viruses or rickettsiae as the cause of the condition.

Dermatophytosis and focal infection have also been suggested as etiologic factors. The evidence for an infectious origin for the disease, though not impressive, is certainly sufficient to encourage further study.

9) *Intravascular Factors* — Hemoconcentration and increased viscosity and increased coagulability of the blood have been reported as precipitating factors in thromboangiitis obliterans. This would lead one to expect intravascular clotting to precede lesions in the walls of the vessels. Actually, though intravascular clotting frequently occurs in Buerger's disease, it is invariably a complication of an already existing inflammatory and obliterative process in the walls of the vessels.

## Pathology

Thromboangiitis obliterans is primarily a disease of the small and medium sized blood vessels of the extremities. It is usually more extensive and more severe in the legs than in the arms. Visceral lesions are rare and usually follow old and extensive peripheral lesions. The disease most commonly involves the anterior tibial, the posterior tibial, and the radial and ulnar arteries; less commonly the plantar, palmar and digital arteries. The small and medium veins are involved less than the arteries. The arterial and venous trunks are involved late in progressive cases, if at all. The arterioles are not affected.

The condition is a distinctly segmental, inflammatory and non-suppurative panarteritis or panphlebitis with associated thrombosis but without necrosis of the vessel wall. Organization of the thrombus occurs vigorously and promptly; recanalization is usually distinctly limited. The lesions in a given case are of different ages, but the involvement of a single segment of a vessel appears to be of a single age. The organic occlusions of the vessels are permanent and essentialy complete. Functionally, the involved vessels are destroyed or hopelessly impaired. There is an extensive development and enlargement of collateral circulation with widespread anas

F Administration of alcohol by mouth b i d or t i d
G Prescription of analgesics, as necessary for relief of pain
H Use of sulphonamides or antibiotics orally or parenterally for systemic action, is indicated

V *Additional measures in cases of extensive gangrene severe ulceration, or osteomyelitis*
A Measures as in IV
B Delay in amputation, if possible until demarcation and possible slough
C Amputation at lowest possible level but with due consideration for the future use of a satisfactory prosthesis and only after patient s condition has been made optimal and infection has been controlled
D Amputation at higher level if
1 Pain is excessive or uncontrolled or
2 Gangrene is spreading

A See section on treatment of acute arterial occlusion
B If circulation is reestablished, follow measures under III
C If gangrene develops use measures under IV or V

## THROMBOANGIITIS OBLITERANS
(Buerger s Disease)

Thromboangiitis obliterans is a specific inflammatory and obliterative disease of the arteries and veins It occurs almost exclusively in young men It involves the extremities (and occasionally the viscera as well) and produces ischemia of the tissues and frequently gangrene Thromboangiitis obliterans involves all three layers of the walls of the vessels This inflammation leads to thrombosis, and organization of the thrombus although it is perhaps, recanalized to a minor extent and transforms the occluded vessel into a fibrous cord

### Etiology

The etiology of thromboangiitis obliterans is not known A number of factors are known to influence both the occurrence and the course of the disease

1) *Age* —Thromboangiitis obliterans manifests itself, for the most part, in men between the ages of 21 and 45 The rare cases of thromboangiitis obliterans among children are found in those who smoke early and heavily Cases in which the condition seems first to manifest itself after the 50th year usually prove to be cases of arteriosclerosis obliterans

2) *Sex* —The disease occurs almost exclusively in men The number of reported cases among women are very few but are recently increasing This may indicate either an increase or better recognition of the disease In many of the cases among women no pathological evidence is submitted to substantiate the diagnosis There is no satisfactory explanation for the rarity of thromboangiitis obliterans among women but there are three theories about it (*a*) that differences in the habits and exposures of the two sexes account for it (*b*) that a sex linked hereditary factor is responsible and (*c*) a biological difference provides women with immunity to the disease

3) *Race* —Thromboangiitis obliterans occurs in all racial groups so far studied It appears to be somewhat more common among Jews than among others but is not as originally thought a disease confined almost exclusively to them

4) *Heredity* —There are only isolated instances of the occurrence of the disease in two or more close relatives

5) *Occupation Trauma Cold* —Repeated studies have failed to show any relationship between the occurrence of thromboangiitis obliterans and occupation even when the occupation is arduous and involves exposure to extreme cold and dampness Trauma is often an aggravating factor and may produce a lesion which by reason of failure to heal normally may first indicate the presence of an extensive obliterative vascular disease Frostbite and fungus infections between the toes may

deal of disagreement about the reported findings and their interpretation

The primary physiological effects of thromboangiitis are impaired blood flow and the resultant ischemia. Impairment of the blood flow may be increased by extensive arteriolar spasm. In cases complicated by thrombophlebitis venous obstruction may contribute to the damage. Changes in the capillaries are not consistent, but atony and dilatation are frequent. These are expressed clinically by intense rubor. Edema is not uncommon. It may result from increased capillary permeability or from increased capillary pressure due to venous stasis and the effects of dependency. Inflammatory reactions may contribute to the edema.

## Clinical Signs

1 *Premonitory Symptoms* — Minor sensory disturbances frequently presage the appearance of the classical symptoms of thromboangiitis obliterans. These include sensations of coldness, burning, formication, tingling, and other types of paresthesias.

2 *Pain* — Pain is ordinarily the presenting symptom and may be one of several types.

*a) Intermittent Claudication* — Claudication is observed in about 75 per cent of the cases and is in general the same as in arteriosclerosis obliterans.

*b) Rest Pain* - Pain at rest, particularly nocturnal pain, is usually described as burning, aching or gnawing and is commonly associated with tenderness. It is often relieved by hanging the affected limb over the side of the bed or by walking about the room. It is often a sign that ulceration or gangrene is imminent.

*c) Pain from Ulcers or Gangrene* — Pain associated with ulceration or gangrene is often severe. It is either continuous or paroxysmal and is often worse at night. Hypesthesia in the area of pain is frequent.

*d) Pain from Inflammation of the Blood Vessels* — Pain from inflammation of the arteries is severe and diffuse. It is often accompanied by signs of localized inflammation. It may produce generalized aching. Pain from the phlebitis which so commonly complicates thromboangiitis obliterans dif-

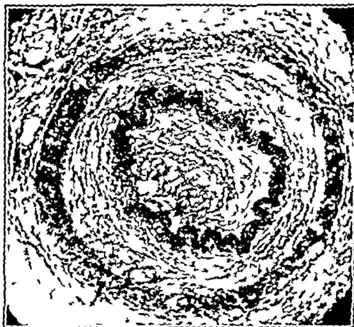

Fig 175 — Thromboangiitis obliterans. The lumen is closed by fibrous tissue which is partially canalized. Hypertrophy of elastica. Elastic tissue stain × 40 (Boyd Textbook of Pathology)

tomoses Ischemia and malnutrition of the tissues are complicated by the effects of trauma and of secondary infection The severity of the disease is in proportion to the speed and extent of the vascular obliteration The outcome in any given case depends largely on the rapidity and completeness with which the active process is suppressed and the collateral circulation is developed

*Gross Changes in the Vessels* —The vessels are contracted the involved segments distinctly indurated The occluding mass in the lumen of the vessel is distinct from the media There may be fresh red thrombus at one or both ends of the older, adherent clot Occlusion of the arteries is the rule that of the veins the exception The extent of occlusion varies, *there may be lengths of* patent lumen between two occlusions Induration usually extends into the adventitia and perivascular tissues and may involve the accompanying vein and nerve as well as the artery

*Histological Changes* —Early changes appear to consist of intimal proliferation focal infiltration of lymphocytes into the intima, and infiltration of lymphocytes and fibroblasts into the adventitia, particularly in the region of the vasa vasorum

In the acute lesions endothelial proliferation is marked and focal intimal infiltration by *lymphocytes usual The lumen is filled* with a thrombus containing endothelial cells and fibroblasts The internal elastic lamina is preserved The medial coat contains fibroblasts and the dilated capillaries in this layer show endothelial proliferation The muscle fibers are usually well preserved There is extensive fibroblastic proliferation in the adventitia, *and the vasa vasorum* are surrounded by foci of lymphocytes The intima of the vasa vasorum proliferates and the medial coat is thickened Leukocytes appear only in small numbers

In old lesions the thrombus becomes increasingly well organized and there is a lack of generalized or extensive canalization The internal elastic lamina is thickened but relatively intact and the *media is not* significantly altered except for infiltrations by fibroblasts and the development of vasa vasorum The earlier fibroblastic reaction in the adventitia is gradually organized *into fibrous connective tissue Fibrosis* characterizes the late lesions and perivascular fibrosis often binds the arteries to vein and nerve The lesions in the veins are similar to those in the arteries

The most striking features of thromboangiitis obliterans are the extensive endothelial proliferation and the dense fibroblastic infiltration The thrombus is a true thrombus although proliferation of the endothelium contributes to the obliteration of the lumen The general architecture of the vessel is discernible in old lesions, despite the intensity of the reaction

*Secondary Pathological Changes* — Ischemia abetted by trauma and infection, produces secondary changes in many tissues *Skeletal structures show the effect of ischemia* there may be atrophy and fibrosis of skeletal muscles osteoporosis of the bones replacement of subcutaneous fat by fibrous tissue and atrophy and distortion of the skin and nails Capillaries, especially those of the digits, may become dilated and atonic

Significant changes in the nerves are common in advanced cases of Buerger s disease There are usually both perineural and perivascular fibrosis and there may be Wallerian degeneration and demyelination Occasionally *the destruction of a nerve may be complete*

Though ulceration and gangrene may occur spontaneously as a result of ischemia these are commonly precipitated by trauma They usually attack the toes but sometimes the fingers the distal half of the foot the entire foot or even the lower leg Ulceration of the foot or leg without involvement of the *toes is almost always due to local trauma* Gangrene is usually dry but may be complicated by secondary infection suppuration or cellulitis with or without lymphangitis

## Pathologic Physiology

The changes in the blood are said to include (1) hemoconcentration (2) alterations of the coagulation factors (3) abnormal concentrations of lipids and (4) altered oxygen content but there is a good

radial and ulnar arteries by means of the Allen test * (4) testing for reflex dilatation by application of heat to the unaffected limbs or to the trunk (Landis and Gibbons) and (5) sympathetic block. Angiography is occasionally necessary.

### Course

Thromboangiitis obliterans tends to be progressive but the rate of progression varies widely. Occasionally a case exhibiting a favorable course is made worse by arteriosclerosis obliterans. Leading students of this disease agree that victims of it who continue to smoke do badly; those who stop smoking may undergo complete and permanent or at least protracted remission.

### Treatment

(Basic principles outlined in section on treatment of arteriosclerosis obliterans)

I. For all patients total and permanent abstinence from the use of tobacco.

II. For patients with claudication only *see* section on treatment of arteriosclerosis obliterans.

III. For patients with claudication and rest pain or ischemic neuritis but without ulceration or gangrene (see section on treatment of arteriosclerosis obliterans).

A. Use warm cradle; heating box not advocated unless under strict thermostatic control.

B. Use nonspecific foreign protein therapy with typhoid H antigen or a typhoid vaccine.

C. If these measures fail to relieve pain consider advisability of sympathetic blocks or a sympathectomy (sympathectomy is method of choice in the presence of marked vasospasm or Raynaud's phenomenon of the digits).

IV. For patients with ulceration, gangrene or infection (*see* section on treatment of arteriosclerosis obliterans) use medical measures to produce vasodilatation; their failure to produce definite improvement indicates need for early sympathectomy.

V. For patients with gangrene, thrombophlebitis or acute arterial occlusion, *see* section on treatment of these conditions.

* *The Allen Test.*—The patient holds his hands in front of him; the examiner presses with his thumbs the radial artery in each of the patient's wrist. The patient then clenches his hands tightly for 10 or 15 seconds and repeats the process until the blood is squeezed out of his hands. With the radial arteries still compressed the patient partially extends his fingers. The return of color to the hands and fingers is then observed. Where the ulnar artery is patent normal color or reactive hyperemia rapidly replaces the pallor. If the ulnar artery is occluded, pallor persists for a variable period. Patency or occlusion of the radial artery may be demonstrated in a similar manner by occluding the ulnar artery and repeating the test.

Grossly impaired pulsations in the arteries of the arms are unusual in arteriosclerosis obliterans. Impairment of these pulsations in either the radial or the ulnar arteries is very common in thromboangiitis obliterans. Unilateral or bilateral obliteration of the ulnar artery as determined by the Allen test strongly favors a presumptive diagnosis of Buerger's disease.

## ACUTE ARTERIAL OCCLUSION

(Arterial Embolism, Acute Arterial Thrombosis)

Sudden occlusion of an artery may result from the development of an intravascular clot *in situ* (thrombosis) or from the lodgement of an unattached and circulating clot arising elsewhere in the vascular system (embolism). It is one of the most dramatic complications of cardiovascular disease but may occur as the result of a trauma or of a disturbance in the coagulation mechanism of the blood. Occlusion of small and relatively minor vessels may not be serious; occlusion of a major artery may produce gangrene. The differential diagnosis between thrombosis and embolism is often difficult or impossible without exploration of the involved vessel but the distinction is important for emboli most often arise in the heart from mural thrombi which not uncommonly release additional emboli.

### Etiology

The heart is the chief source of systemic arterial emboli. These are usually detached

fers in no essential from that of thrombophlebitis from any cause

*e) Pain from Sudden Arterial Occlusion* — Sudden arterial occlusion produces severe pain that radiates down the limb and is often associated with muscular cramps. The limb peripheral to the occlusion becomes cold, clammy, numb, and either pale or cyanotic. The pulses distal to the occlusion are not palpable. The pain tends to subside in from 24 to 72 hours but may recur upon movement or manipulation of the limb. This pain is undoubtedly due to ischemia resulting from organic occlusion and the associated vasospasm. When the collateral circulation has become adequate and the vasospasm is relieved, this pain disappears. Residual paresthesias, numbness, and tingling, and paroxysms of pain and claudication tend to persist for a long time.

*f) Pain from Ischemic Neuritis* —When the nerves accompanying the involved arteries are damaged by ischemia and the periarterial spread of the inflammatory process, there is often a sharp lancinating pain that radiates peripherally. This pain is often both paroxysmal and diffuse. Section of the involved nerve may be necessary for relief. The pain tends to occur late in the course of the primary disease.

3. *Temperature Changes* —A sensation of coldness may occur in the distal portion of a limb, especially if the limb is exposed to temperatures below room temperature. This coldness may alternate with a feeling of burning that occurs when the limb is warmed.

4. *Color Changes* —The striking rubor with or without cyanosis which appears on dependency in a limb afflicted with occlusive arterial disease is due to compensatory dilatation of the minute vessels which contain blood highly saturated with oxygen. Cyanosis appears as the relatively stagnant blood slowly loses its oxygen to the tissues. Upon elevation of the limb, the rubor yields to pallor as the blood drains out and fresh blood is unable to flow in freely.

In a normal person lying supine, the normal color of the foot is maintained on elevation to 180° and only slight rubor occurs on dependency to 60° or less. Abnormal pallor on elevation can be hastened and accentuated by massaging the foot toward the body and by having the patient move his toes actively. Rubor and pallor usually appear in a patchy manner due to differences in the speed with which the vessels fill and empty. These color changes, even when the pedal pulses are palpable, constitute evidence of arterial insufficiency.

5. *Edema* —Edema commonly occurs in Buerger's disease as a result of (1) obstruction by phlebitis of the venous return, (2) increased intracapillary pressure due to inactivity and dependency, or (3) inflammation.

6. *Phlebitis* —Superficial or deep phlebitis occurs in about half the cases of thromboangiitis obliterans. It may be the initial sign of the disease. Thromboangiitis should always be thought of when phlebitis occurs without clear cause in young or middle aged men, especially if it recurs in the legs or feet.

7. *Trophic Changes* —As a result of impaired blood supply, the skin becomes tense, shiny, dry, scaly, and often pigmented. The nails become thickened, ridged, and discolored and fail to grow.

Ulcers and fissures develop upon the slightest trauma and infection supervenes readily. Fungus infections between the toes produce deep fissures. The ulcers and fissures in thromboangiitis are characteristically deep, sharply demarcated, moist, purulent, inflamed and excruciatingly tender.

8. *Gangrene* —The ulcers and fissures tend to progress to frank gangrene involving the digits or portions of the hand or foot. Occlusion of major vascular channels leads to more or less massive gangrene which is often moist and necrotic. The pain of the gangrene in Buerger's disease is excruciating.

*Differential Diagnosis* — See table p. 1100

## Diagnostic Procedures

Since thromboangiitis obliterans is essentially a systemic vascular disease, the physical examination must be painstaking and should include (1) systematic palpation of the peripheral arteries, (2) oscillometry, (3) determination of the patency of the

radial and ulnar arteries by means of the Allen test,* (4) testing for reflex dilatation by application of heat to the unaffected limbs or to the trunk (Landis and Gibbons) and (5) sympathetic block. Angiography is occasionally necessary.

### Course

Thromboangiitis obliterans tends to be progressive, but the rate of progression varies widely. Occasionally a case exhibiting a favorable course is made worse by arteriosclerosis obliterans. Leading students of this disease agree that victims of it who continue to smoke do badly; those who stop smoking may undergo complete and permanent or at least protracted remission.

### Treatment

(Basic principles outlined in section on treatment of arteriosclerosis obliterans)

I. For all patients: total and permanent abstinence from the use of tobacco.

II. For patients with claudication only: *see* section on treatment of arteriosclerosis obliterans.

III. For patients with claudication and rest pain or ischemic neuritis but without ulceration or gangrene (see section on treatment of arteriosclerosis obliterans):

A. Use warm cradle; heating box not advocated unless under strict thermostatic control.

B. Use nonspecific foreign protein therapy with typhoid H antigen or a typhoid vaccine.

C. If these measures fail to relieve pain, consider advisability of sympathetic blocks or a sympathectomy (sympathectomy is method of choice in the presence of marked vasospasm or Raynaud's phenomenon of the digits).

IV. For patients with ulceration, gangrene or infection (*see* section on treatment of arteriosclerosis obliterans), use medical measures to produce vasodilatation; their failure to produce definite improvement indicates need for early sympathectomy.

V. For patients with gangrene, thrombophlebitis or acute arterial occlusion, *see* section on treatment of *these conditions*.

*The Allen Test.*—The patient holds his hands in front of him; the examiner presses with his thumbs the radial artery in each of the patient's wrist. The patient then clenches his hands tightly for 10 or 15 seconds and repeats the *process until the blood is* squeezed out of his hands. With the radial arteries still compressed, the patient partially extends his fingers. The return of color to the hands and fingers is then observed. Where the ulnar artery is patent, normal color or reactive hyperemia rapidly replaces the pallor. *If the ulnar artery is occluded, pallor* persists for a variable period. Patency or occlusion of the radial artery may be demonstrated in a similar manner by occluding the ulnar artery and repeating the test.

Grossly impaired pulsations in the arteries of the arms are *unusual* in arteriosclerosis obliterans. Impairment of these pulsations in either the radial or the ulnar arteries is very common in thromboangiitis obliterans. Unilateral or bilateral obliteration of the ulnar artery as determined by the Allen test strongly favors a presumptive diagnosis of Buerger's disease.

## ACUTE ARTERIAL OCCLUSION

### (Arterial Embolism, Acute Arterial Thrombosis)

Sudden occlusion of an artery may result from the development of an intravascular clot *in situ* (thrombosis) or from the lodgement of an unattached and circulating clot arising elsewhere in the vascular system (embolism). It is one of the most dramatic complications of cardiovascular disease but may occur as the result of a trauma or of a disturbance *in the coagulation mechanism* of the blood. Occlusion of small and relatively minor vessels may not be serious; occlusion of a major artery may produce gangrene. The differential diagnosis between thrombosis and embolism is often difficult or impossible without exploration of the involved vessel, but the distinction is important, for emboli most often arise in the heart from mural thrombi which not uncommonly release additional emboli.

### Etiology

The heart is the chief source of systemic arterial emboli. *These are usually detached*

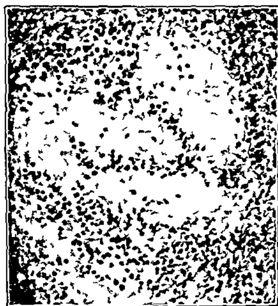

FIG 176 —Fresh pale thrombus on ventricular endocardium composed of leukocytes and platelets (pale areas) Photomicrographs (Bell Textbook of Pathology )

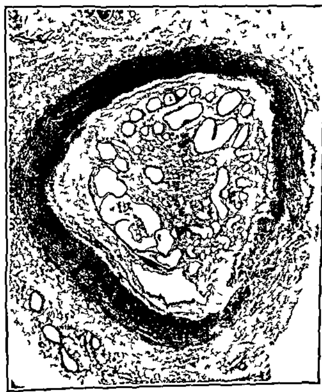

FIG 177 —An arterial thrombus showing canalization Photomicrograph (Bell Textbook of Pathology )

portions of intracardiac mural thrombi occurring in rheumatic heart disease with auricular fibrillation, myocardial infarction with mural thrombosis, acute or subacute bacterial endocarditis involving the mitral or aortic valves, and congestive heart failure. Emboli may arise in the arteries themselves from thrombi associated with aneurysms, arteriosclerotic plaques, trauma or inflammation. Occasionally paradoxical emboli arise in the systemic veins and pass into the systemic arteries through a patent foramen ovale when the pressure in the right auricle is increased.

Localized thrombosis in an artery may result from an inflammatory disease such as thromboangiitis obliterans, periarteritis nodosa or mycotic arteritis; from the degenerative disease arteriosclerosis obliterans; from trauma such as gunshot and stab wounds or severe extrinsic trauma; or from pressure as that exerted by a cervical rib. Thrombosis occurs with unusual frequency in connection with certain infectious diseases (*e.g.*, typhoid fever, pneumonia, *etc.*) with blood dyscrasias (especially polycythemia) and with heart disease producing congestive heart failure. It is also an important sequel to extensive surgical procedures. Sudden and severe multiple arterial occlusions associated with an increased coagulability of the blood and an increased platelet count have been described as *idiopathic thrombophilia*.

## Pathology

Except under experimental conditions it is unlikely that thrombosis is ever the result of a single factor.

In general, three important mechanisms predispose to thrombosis: disturbances in the integrity of the endothelial lining of the vascular tree, as by inflammation or trauma; disturbances in the blood flow, systemically, as in congestive heart failure, or locally, as by extrinsic pressure or intrinsic disease (*e.g.*, arteriosclerosis); and alterations in the coagulability of the blood. Hypercoagulability of the blood may be systemic, as when hyperprothrombinemia exists, or local, as when the output of thromboplastin is increased by local tissue damage.*

## Clinical Signs

Pain in acute arterial occlusion may occur abruptly and be excruciating. But it may occur gradually and not be severe at all. Numbness, coldness and tingling occur in various combinations, however, with or without pain. Occasionally there is loss of muscular power.

The affected limb soon becomes pale and either remains so, assuming a patchy cyanotic pallor, or regains its color only gradually. This depends on the efficiency of the collateral circulation and the relief of the associated vasospasm. The pulse is often lost for a considerable distance proximal to the actual occlusion; this is due presumably to vasospasm, for the pulse returns as vasospasm is relieved.

The chief clinical findings are (1) lowered surface temperature distal to the occlusion, (2) collapsed superficial veins, (3) pallor, (4) diminished reflexes, (5) impaired sensation, (6) loss of muscular strength, and, most important, (7) sudden absence of arterial pulsations previously present.

Systemic manifestations vary widely and in the main depend on the general condition of the patient and the nature of coëxisting disease. In many cases the symptoms of the primary disease overshadow the manifestations of the occlusion; in others the patient becomes suddenly worse as the result of acute occlusion and may go into actual shock.

## Course

The duration of the symptoms that follow an acute occlusion also varies widely; it chiefly depends on the effectiveness of the collateral circulation and the relief of vasospasm. If marked vasodilatation occurs or

* Polycythemia vera, a hematogenous disease, is often associated with peripheral vascular diseases. Thrombophlebitis and sudden arterial occlusion by thrombosis are common complications of polycythemia. Patients with polycythemia usually die of intravascular thrombosis. Occasionally thromboangiitis obliterans is associated with polycythemia.

can be induced, the symptoms may be relieved in a matter of a few hours Symptoms *ordinarily subside* spontaneously in from 24 to 72 hours but either recovery or gangrene may follow In many cases the symptoms of acute occlusion merge into those of ischemic neuritis, the severe paroxysmal pain of which may persist for weeks or months Even when recovery occurs without gangrene or ischemic neuritis, certain stigmata of impaired arterial circulation—vasomotor changes, coldness, intermittent claudication and hyperesthesia—are likely to remain

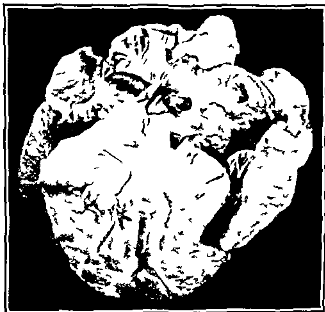

Fig 178 —Paradoxical embolism Heart showing an embolus which was passing from the right auricle through a patent foramen ovale (Bell Textbook of Pathology )

## Prognosis

The prognosis in acute arterial occlusion depends on (1) the artery involved and the level at which it is involved (2) the kind of occlusion—*i e* whether it is due to thrombosis or emoblism (3) the degree of associated vasospasm and the speed with which it is relieved, (4) the efficiency of the collateral circulation, once vasospasm is relieved, (5) the age and general physical condition of the patient (6) the nature of the primary disease and its influence on the general condition of the patient his vascular tree, and his local tissues (7) the promptness and efficiency of treatment

If only the simplest conservative treatment is applied to acute arterial occlusions of major arteries in the extremities, about half the cases will develop gangrene Diagnosis and treatment must be prompt

Age *is an important consideration for* older patients are usually in poorer general condition than younger ones and develop collateral circulation less readily besides they usually exhibit circulatory impairment as a result of atheromatous changes Gangrene occurs in more than three quarters of the patients over 60 but only in slightly more than a third of those under 60

When arterial thrombi occur in patients suffering from severe infections or congestive heart failure the prognosis is generally poor for the intravascular clotting usually indicates failing circulation In these cases peripheral *thromboses are often followed by* pulmonary embolism cerebral vascular occlusion or coronary thrombosis When simple thrombosis occurs after trauma or an operation the prognosis is relatively good

TREATMENT

The immediate treatment is as follows

1) The patient is put to bed in a hospital room maintained at a temperature of from 80 to 85° F

2) If available an oscillating bed is used Otherwise the head of the hospital bed is elevated on blocks 6 inches high

3) The patient's foot and leg are wrapped loosely in cotton batting but neither heat above 90° F (32 2° C) nor refrigeration are applied directly to the involved extremity (Refrigeration may be used as preamputation anesthesia)

4) Reflex heat is applied to the abdomen or to the lumbosacral area by means of a heating pad

5) Morphine or a morphine substitute is given parenterally to relieve pain Relief of vasospasm (*see* below) may so improve the circulation as to make opiates unnecessary after the *initial* period of treatment

6) Vasospasm is relieved and maximum vasodilatation obtained as follows

*a*) Whiskey or brandy is given (1 or 2 ounces) every 3 to 6 hours depending on the tolerance of the patient

*b*) Papaverine hydrochloride 0 5 to 1 0 grain (0 03—0 06 gram) is given intravenously or intra-arterially proximal to the occlusion The injection of 1 grain of papaverine directly into the brachial or femoral arteries will frequently produce a striking increase in warmth and occasionally a conspicuous flush in extremities which have previously been cold and cyanotic Such a response may occur in limbs which have not responded to a sympathetic block The injection may be repeated every 4 to 6 hours if the response is good but not so often as to produce drowsiness or disorientation The intra-arterial injection must be made cautiously

*c*) Paravertebral sympathetic block is performed This may produce satisfactory peripheral vasodilatation but must be repeated several times within the first 2 or 3 days to maintain the effect

*d*) Sympathetic blocking agents are used (either tetraethylammonium chloride [Etamon®] in doses of from 3 to 10 cc intramuscularly every 3 to 6 hours or *Priscoline®* in doses of from 50 to 100 mg parenterally at similar intervals)

Sympathectomy is performed if severe vasospasm persists despite more conservative measures The results of sympathectomy cannot be predicted from the effects of the sympathetic blocking agents or of paravertebral blocks

7) Anticoagulants are used to prevent propagation of the intravascular clot and further thromboembolic phenomena To produce a prompt anticoagulant effect heparin should be administered immediately and Dicumarol® also if the patient is to be maintained on the latter drug The anticoagulant therapy may be delayed or interrupted briefly if surgery is performed immediately

8) The cause of the acute arterial occlusion (as also the source of the embolus in instances of embolism) is ascertained If this is found to be an intracardiac mural thrombus as in cases of rheumatic heart disease with auricular fibrillation further thromboembolic episodes may be anticipated unless long term anticoagulant therapy is used

9) Embolectomy is done if a massive embolus occurs in a major arterial trunk or bifurcation (as in the aortic bifurcation where the result is total blocking of the iliac arteries and paralysis and coldness of the legs) If done at all the operation should be done from 4 to 10 hours after the occurrence of the embolus Anticoagulant therapy should be used postoperatively

In favorable cases the patient is kept in bed in a warm environment until the circulation has become adequate An oscillating bed if available is used for eight hours a day or more Alcohol sedatives analgesics and sympathetic blocking agents may be continued until the circulation is reestablished

If gangrene develops the infection should be controlled by the use of antibiotics locally and systemically Amputation if necessary should be performed at the optimum time

## OTHER DISEASES OF THE ARTERIES

### Aneurysms

An aneurysm, the abnormal dilatation of a blood vessel, results from localized weakness in and consequent stretching of the vessel's wall. The term is restricted to arterial aneurysms, most venous dilatations are called *varicosities*. The term *aneurysm* should not be applied to arteriovenous fistulas, in combination with which aneurysms not uncommonly occur.

Table 52.—Etiological Classification of Aneurysms

*A* Arteriosclerosis
*B* Syphilis
*C* Other infections (Mycotic aneurysm) *e g* tuberculosis actinomycosis septicemia subacute bacterial endocarditis typhoid fever *etc*
*D* Congenital weakness of the arterial wall *e g* in the anterior portion of the Circle of Willis and its branches
*E* Trauma producing either true or false aneurysms with or without arteriovenous fistulas
*F* Periarteritis nodosa and other necrotizing arteritides usually producing small aneurysms

Table 53.—Pathological Classification of Aneurysms

| | |
|---|---|
| Fusiform aneurysm | A rather uniform spindle shaped or fusiform dilatation of a segment of an artery |
| Saccular aneurysm | A definite sacculation or outpouching from an artery results from a highly localized weakness of the media |
| Dissecting aneurysm | Rupture of the inner layers of the wall of an artery permits the blood to dissect for varying distances between the inner and outer layers of the wall. At the distal end of the dissection communication with the lumen may be re-established or rupture may occur into the surrounding tissues or body cavity |
| False aneurysm | Complete rupture of all coats of the artery, occurs with the formation of a sac the walls of which are composed of successive layers of blood clot. Especially common in the popliteal space |

### Pathology

*Arteriosclerotic Aneurysms.*—An arteriosclerotic aneurysm usually forms when the medial coat of an artery undergoes focal destruction and the muscle fibers are replaced by fibrous tissue. This may occur in any artery. In the early stages all arteriosclerotic aneurysms are fusiform or saccular. There is a tendency for dissection to follow, and, not infrequently, false aneurysms are formed. Saccular aneurysms are most commonly found in the abdominal aorta and popliteal arteries. Fusiform aneurysms are most common in the thoracic and abdominal portions of the aorta. Dissecting aneurysms are generally confined to the aorta, of which they may involve any portion, and even involve its branches. Arteriosclerotic aneurysms usually occur in persons over 50 and are most common in men. Complete rupture is uncommon but thrombosis is a frequent complication.

*Syphilitic Aneurysms.*—The aneurysms of tertiary syphilis are confined almost exclusively to the aorta and are most frequently found in the ascending portion and the arch. Sometimes, however, they involve the abdominal aorta and occasionally the peripheral vessels. These aneurysms probably result from inflammatory lesions involving the vasa vasorum, impaired nutrition of the media results in focal degenerative changes. Leutic aneurysms are fusiform or saccular, they may enlarge rapidly or very slowly (over a period of years). Some become enormous and eventually erode through resistant structures. Death not uncommonly follows rupture of such an aneurysm, massive hemorrhage occurs into one of the body's cavities or tracts.

*Mycotic Aneurysms.*—These occur in arteries involved in suppurative processes which weaken the media to the point of dilatation or rupture. Local abscesses are a common site of aneurysm formation. A mycotic aneurysm tends to occur where the artery is relatively unsupported by skeletal

TABLE 54 — CHARACTERISTICS OF ANEURYSMS ACCORDING TO THEIR COMMON SITES

| *Type and Location of Aneurysm* | *Common Etiologies* | *Average Age of Appearance* | *Sex Preponderance* | *Prognosis* |
|---|---|---|---|---|
| AORTA | | | | |
| Dissecting Aneurysm | Arteriosclerosis usually syphilis uncommonly Hypertension present in 50 60 % of cases | 60 years | Males 6 1 | Sudden death 33% Death within 24 hours 50% Survival for 1 month 10% |
| Saccular and Fusiform Aneurysm Thoracic Aorta | Syphilis in the majority of cases less commonly arteriosclerosis rarely trauma | 60 years | Men 4 1 | Av length of life without antiluetic therapy 1-2 years with treatment 5 years or more |
| Saccular and Fusiform Aneurysm Abdominal Aorta | Majority due to arteriosclerosis 5-10% due to syphilis other causes rarely | 60 years | Males 2 1 | Prognosis somewhat better than for thoracic aneurysm |
| INTRA ABDOMINAL ARTERIES OTHER THAN THE AORTA | Most common causes are mycotic or necrotizing arteritis or periarteritis nodosa | Any age | No significant sex variation | Prognosis is largely dependent on underlying disease |
| LARGE ARTERIES LOWER EXTREMITIES | Most common cause is arteriosclerosis in younger persons arteritis and trauma | Any age | No significant sex variation | Prognosis is relatively good Ligation and obliteration usually possible |
| LARGE ARTERIES UPPER EXTREMITIES OR NECK | Trauma commonly arteritis or arteriosclerosis uncommonly | Any age | No significant sex variation | Prognosis relatively good Ligation and obliteration often possible |
| SMALL PERIPHERAL ARTERIES | Usually due to periarteritis nodosa | Any age | No significant sex variation | Prognosis is that of underlying disease Lesion usually can be excised for diagnosis |

FIG 179 — Aneurysm of the aorta (Boyd Pathology of Internal Diseases)

muscle and is subject to frequent bending, as in the *popliteal, femoral, axillary*, and brachial arteries and in Scarpa's triangle

*Aneurysms Due to Periarteritis and Necrotizing Arteritis.*—Local muscular necrosis in small and medium-sized arteries results in small aneurysms that give the vessels a nodular or beaded appearance. The nodular lesions of temporal arteritis are often tiny aneurysms. Localized intimal proliferation and localized periarteritis occur here. The aneurysms may be true or false and may develop progressively in widely distributed arteries. There is no evidence of bacterial infection in these cases.

*Congenital Aneurysms.*—When a congenital aneurysm exists, the medial coat is absent or thin and underdeveloped in segments of an artery. Congenital aneurysms are rather common in the Circle of Willis and its branches and in the intracranial portion of the internal carotid arteries. Rupture of such an aneurysm is one of the common causes of fatal cerebral hemorrhage. Congenital aneurysms may be multiple. In one case observed, they were present in both popliteal arteries, both axillary arteries and the aorta. They may also be found in association with hemangiomas and with congenital arteriovenous fistulas.

*Traumatic Aneurysms.*—True or false aneurysms, more commonly the latter, may be caused by penetrating wounds. Even when there is only slight external bleeding a hematoma may form and develop into a false aneurysm.

## DISSECTING ANEURYSM

### Clinical Signs

The onset is sudden and often associated with physical exertion or emotional strain. The pain is usually excruciating and is commonly precordial so that it may be ascribed to acute coronary occlusion. The pain however may originate between the scapulae, in the abdomen or in the lumbar region. It tends to spread from front to back or vice versa, and then down into the abdomen or the legs. It may radiate to the neck, sometimes (though seldom) to the arms. The pain may persist for days. Occasionally, the attack is painless and manifested by acute cardiac failure due to aortic reflux. Shock, collapse and severe vomiting are usual. Further signs depend on (1) the degree of pressure on adjacent structures and (2) the degree of interference with the blood flow through the branches of the aorta.

Pressure on the great veins may produce venous engorgement and cyanosis. This may be asymmetrical, so that the venous pressure is different for each arm. Pressure on the recurrent laryngeal nerve may cause aphonia, on the esophagus, dysphagia, and on the lung, dyspnea, collapse of the lower lobe and pleural effusion.

Involvement of the orifices of the innominate or the subclavian arteries may alter the radial pulse. Involvement of the carotid arteries may produce syncope and hemiplegia. Involvement of the renal arteries may result in hematuria, or anuria. Loss of normal arterial pulsation in the extremities may in combination with the above signs suggest the diagnosis. The limbs may become pale, cold, cyanotic and numb. Frequently there is loss of motor function and the reflexes are depressed or suspended.

Dissection into the pericardial sac or the pleural cavity usually causes immediate death. The orifices of a coronary artery may be involved; this leads to coronary occlusion with myocardial infarction. Involvement of the root of the aorta renders the valves incompetent and new murmurs appear. The left ventricle dilates acutely and intractable heart failure may supervene.

### Course

Many patients die at once, but some survive. Recovery may even be sufficiently complete to permit a life of reasonable activity for months or years.

### Diagnosis

An onset of precordial pain may suggest coronary occlusion. The diagnosis of dissecting aneurysm is practically certain if three cardinal groups of signs appear:

1) loss of circulation and motor function in the legs

2) evidence of pressure on contiguous structures and
3) previously absent aortic murmurs

### Laboratory Findings

The roentgen examination of the chest will frequently disclose an irregular shadow of variable density on the left side. Pulsations may or may not be evident or may change from time to time. An electrocardiogram may rule out coronary occlusion with myocardial infarction unless this has occurred as a complication. There may be some degree of leukocytosis and of anemia. The urine may show hematuria if the renal arteries are involved, or there may be anuria.

Fig 180.—Dissecting aneurysm of abdominal aorta. The media is split into two layers by a mass of blood. ×15. (Boyd, Pathology of Internal Diseases.)

## NON-DISSECTING ANEURYSM

Common sites of arteriosclerotic aneurysms are the aorta and the popliteal, innominate, subclavian and common carotid arteries.

Symptoms of non-dissecting aneurysm of the aorta vary widely, depending on the etiology, size, shape and location of the aneurysm. Though aneurysms may be painless until they reach considerable size, pain due to pressure and traction on surrounding structures is a common symptom. It is often substernal and may be transmitted to the neck, shoulders, arms or back. It may be severe. Large aneurysms may obstruct the vena cava. There may also be symptoms as a result of tracheal or bronchial obstruction, among them dyspnea and a brassy cough. Pressure on the recurrent laryngeal nerve may produce hoarseness. There may be numbness in the arms. A systolic murmur with or without a diastolic component is commonly heard over the aortic area. There may be widening of the upper mediastinum on percussion.

Abdominal aneurysms are symptomless in about half of the cases. They may be painful, however, the pain being felt in the abdomen or lower back. Numbness or weakness of the legs may occur. The aneurysm can frequently be palpated as a pulsating mass. A systolic bruit is present in a few cases. Aneurysms of intra-abdominal vessels other than the aorta are not often diagnosed during life except at the time of laparotomy. However, the routine use of the stethescope over areas other than the heart and lungs has resulted in discovery of intra-abdominal aneurysms.

Aneurysms of the arteries of the arms and legs usually produce no acute symptoms unless *rupture occurs*. *Pain occurs upon* rupture, during periods of rapid enlargement, or as a result of pressure on a nerve. This last may cause paresthesias or paralysis. Pressure on a vein may produce venous obstruction and insufficiency. Sudden arterial occlusion as a result of thrombosis or embolism commonly occurs in the aneurysm or distal to it. The diagnosis is usually not *difficult if the* aneurysmal dilatation is palpable. An expanding pulsation in a vessel definitely wider than normal is pathognomonic. A systolic bruit can sometimes be heard.

### Laboratory Findings

Roentgen examination is the most valuable *procedure in diagnosing* an aneurysm and in delineating its size, shape, and location. Pulsations are often visible in aneurysm of the thoracic aorta but owing to thickening of the wall by blood clot may not be. In the absence of pulsations, a typical location, size, and shape are often sufficient identification. X rays are also of value in abdominal aneurysm. The characteristic picture is that of a tumor *in* the region of the aorta, a tumor with a thin line of calcium in its wall. In questionable cases, *contrast angiography of the aorta (aortography)* can be performed. Radiological examination of arteriosclerotic aneurysms in peripheral vessels is diagnostic when the expanded arterial wall is delineated by a thin line of calcification. Angiography is most useful in localizing and delineating aneurysms of peripheral arteries.

### Treatment

There *is no* medical treatment for aneurysms *per se*. Symptomatic and palliative measures are indicated. In a case of luetic aneurysm, however, the syphilis should be treated conservatively with an initial course of bismuth followed by *carefully graded* doses of arsphenamine. When fully evaluated penicillin may be the therapeutic agent of choice. Surgical measures developed for the extirpation or eradication of aneurysms in various locations are frequently indicated but are beyond the scope of this discussion.

## ARTERIOVENOUS FISTULAS

An arteriovenous fistula is an abnormal *communication* between *an artery* and a vein. It may be either congenital or acquired; if the latter, it is most commonly the result of a gunshot wound, a knife wound, or a flying projectile wound.

### Congenital Arteriovenous Fistula

*Etiology*.—Congenital arteriovenous fistulas arise from the failure of the common embryological anlage to differentiate into artery and vein.

*Pathology*.—Arteriovenous fistulas, whether congenital or acquired, may occur anywhere *in the body*. *Each anastomosis may have* one or more of the following characteristics: (1) a direct communication between an artery and a vein, (2) an aneurysmal sac between an artery and a vein, (3) an aneurysmal sac on the arterial side with a communication to the vein, (4) a common opening from an artery and a vein into an aneurysmal sac. In the congenital type, there may be large pools or sinuses with which surrounding arteries communicate through multiple channels. These venous *sinuses or tracts eventually empty* into definite veins.

### Sites

Most demonstrable congenital fistulas occur in the extremities, but they may occur elsewhere. They are apt to be multiple when in the extremities. All types of organs and tissues may be involved, including the viscera and the bones. Similarly, all regions of the body, including the cranium and its content, may be the site of fistulas.

### Clinical Signs

(1) Varicose veins are almost always present in association with congenital arteriovenous fistula, and their occurrence at an early age should always suggest this diagnosis. (2) Ulceration or gangrene may

occur (3) A port wine nevus (birthmark) often indicates congenital arteriovenous fistula When on one of the extremities such a birthmark should especially suggest such a communication (4) There is usually an exaggerated growth of hair and increased sweating in regions affected by congenital fistula (5) An increased length of the limb is also usual (6) The temperature of the skin of the affected member is usually higher than that of the contralateral normal extremity (7) Compression of the artery above the site of a fistula usually slows the heart rate by from 5 to 50 beats a minute (8) The oxygen content of the venous blood in the vein proximal to the fistula is increased (this is demonstrated by its bright red color and high degree of oxygen saturation) (9) The lesion may frequently be demonstrated conclusively by arteriography

## ACQUIRED ARTERIOVENOUS FISTULA

### Clinical Signs

*Immediate Manifestations* —A wound which produces the fistula usually bleeds profusely A thrill and bruit continuous through the cardiac cycle appear immediately or after some hours or days

*Delayed Manifestations* —(1) Relative venous insufficiency may be manifested by the appearance of varices edema stasis pigmentation chronic indurative cellulitis and ulceration The ulceration of arteriovenous fistula may affect the distal part of the foot an unusual location for ulceration from ordinary chronic venous insufficiency (2) Gangrene of the digits or the area distal to the shunt may occur as a result of ischemia (3) A disproportionate increase in the length of the limb may occur in cases in which the fistula is acquired before the epiphyses close (4) Thrill and bruit continuous through the cardiac cycle accentuated during systole and of a coarse machine-like quality are pathognomonic (5) The temperature of the skin of the extremity distal to the fistula is usually warmer than that of the normal limb at corresponding levels This is invariably true in the neighborhood of the fistula and commonly so of the toes (6) There may be cardiac enlargement though this is often not marked If the fistula is large cardiac failure may occur

### Diagnosis

Suspect traumatic arteriovenous fistula whenever (1) varicose veins are marked unilateral or not otherwise readily explicable (2) chronic venous insufficiency appears after an injury (3) one limb is warmer and or longer than its companion (4) the patient is aware of a murmur in the region of a penetrating wound The presence of the typical continuous thrill and bruit is diagnostic and confirmatory findings include those already enumerated

### Laboratory Findings

The following laboratory findings are valuable (1) increased oxygen saturation of the venous blood in the region of or proximal to the fistula (2) increased venous pressure in the veins leading from the shunt (3) increased cardiac output (4) increased blood volume (5) increased oscillometric readings distal to the shunt in most instances (6) characteristic arteriographic findings which will demonstrate the site of the lesion its extent and perhaps the mechanism of the circulation below the shunt

### Treatment

When arteriovenous fistulas are single or few in number they can be excised successfully But the problem is often complicated by the fact that the communications are numerous Ligation of the artery proximal to the site of multiple communications or simultaneous ligation of the artery and the vein are of little value When a single digit is involved amputation is advisable Treatment with radium is useful when the radium can be applied to superficial angiomatous regions over the dilated vessels Occasionally injection of the superficial vein with sclerosing solutions such as those used in the treatment of varicose veins may be of value A simple yet sometimes satis

factory method of treatment, particularly when the fistulas are in the legs or feet, is that of compressing the abnormal connections by rubber or elastic bandages

The treatment in most cases is surgical

## COARCTATION OF THE AORTA

Coarctation of the aorta is a localized narrowing of the aorta, usually in the vicinity of the insertion of the ductus arteriosus, which sometimes remains patent There are two chief types of coarctation the infantile and the adult, although all degrees of gradation occur between these

### Etiology

Coarctation of the aorta is a congenital anomaly or developmental defect The infantile type which is uncommon consists of a narrowing of the entire isthmus that part of the aorta between the left subclavian artery and the ductus arteriosus and sometimes of the proximal portion of the arch as well During fetal life the isthmus remains hypoplastic since blood enters the descending aorta largely through the ductus arteriosus This fetal condition may persist for a few weeks or months after birth but it rarely persists until adult life In the infantile type of coarctation the hypoplasia of the isthmus persists and the isthmus may be no more or little more than a fibrous cord

The adult type of coarctation consists of a very localized constriction of the aorta at or near the insertion of the ductus arteriosus It is much more common than the infantile type The ductus arteriosus may remain patent or there may be other associated cardiovascular anomalies All grades of narrowing occur from slight to complete obliteration of the lumen

### Incidence

Coarctation of the aorta one of the half dozen more common congenital anomalies was present in 142 of the 1000 cases of congenital cardiovascular defects reported by Abbott In her series 37 cases were of the infantile type and 105 cases of the adult type The defect has been noted more frequently in the male than in the female

### Pathological Physiology

The proximal part of the aorta may be hypoplastic, or dilated and is often involved in atheromatous degeneration The aortic valves are commonly bicuspid and may become calcified The blood pressure in the arms is usually elevated but as a result of anomalies in the great vessels, may be different in each arm Usually hypertrophy of the left ventricle eventually occurs The smaller arteries and arterioles of the arms are normal

The cause of the hypertension of the upper part of the body is thought to be due to a decrease in the renal blood flow Since glomerular filtration is normal the interference is thought to be in the glomerular efferent arterioles and to be rather like an arteriospasm The cardiac output is increased in most cases but may be normal unless heart failure supervenes The peripheral blood flow is high

The systolic blood pressure is reduced distal to the coarctation and in the legs but the diastolic pressure may remain normal The pulse in the legs is usually weak and retarded In some cases neither the blood pressure nor the pulses in the legs can be obtained by clinical methods

The collateral circulation consists of anastomoses between the aorta and the following arterial systems scapular cervical internal mammary intercostal and spinal When the ductus arteriosus is patent a collateral circulation may not develop

*Symptoms* —In the adult type of coarctation there may be neither symptoms nor signs Symptoms may develop only after years and then be referable to the hypertension, to cardiac failure or to other complications

### Signs

In highly developed coarctation there are a number of important physical signs (1) inequality in blood pressure and pulse between the arms and the legs (the brachial

systolic pressure is ordinarily much elevated, the femoral systolic pressure low, and the femoral pulse small); (2) evidence of collateral circulation between the upper and lower parts of the body, the vessels being dilated and tortuous and sometimes exhibiting palpable or visible pulsations; (3) prolonged systolic murmurs, often accompanied by thrills, felt over the precordium and back and often along the dilated tortuous anastomotic vessels; (4) enlargement of the heart and sometimes heart failure due to associated cardiac lesions and to the hypertension itself.

### Course and Complications

The course of patients with coarctation varies tremendously, depending on the degree of the narrowing of the aorta, the associated cardiovascular anomalies, and the occurrence of complications. The death of such patients early in life usually occurs as a result of congestive heart failure, rupture of the aorta, cerebrovascular accident, or bacterial endarteritis.

### Laboratory Findings

The roentgen examination of the chest, utilizing the oblique as well as the anteroposterior position, is invaluable in demonstrating the presence and characteristics of coarctation. There is a decrease in the size of, or an absence of, the aortic knob, frequent evidence of dilatation of the ascending aorta, and in advanced cases notching of the ribs. Of critical value is the use of retrograde aortography.

### Diagnosis

The diagnosis of coarctation should be considered in all instances of unexplained hypertension. It is to be suspected particularly when hypertension occurs in childhood or youth. In advanced cases the differences in blood pressure and pulse between the arms and legs, the prolonged systolic murmur widely transmitted down the back and often accompanied by thrill, and the evidence of collateral circulation make the diagnosis relatively simple.

### Treatment

Many cases of coarctation can now be corrected surgically by excision of the constricted area and anastomosis of the aorta or by insertion of an arterial graft.

### Prognosis

Patients with coarctation may live to an advanced age but are always liable to sudden death from rupture of the aorta or of the commonly associated congenital aneurysm of the cerebral circulation, from serious illness, or from cardiac failure or endarteritis. The average life span of persons with untreated coarctation is about 30 years. The surgical treatment seems to offer hope of an increased life span, but longer periods of observation are essential for final conclusions.

## DISEASES OF THE VEINS

The organic diseases of the veins may be divided into the obstructive and the nonobstructive. The first include those due to intrinsic occlusion, as in venous thrombosis and in neoplastic invasion of a vessel, and those due to extrinsic pressure, as from a gravid uterus, a growing malignant tumor, or the wearing of constricting garments. By far the most common lesions of this type are the two forms of venous thrombosis, thrombophlebitis and phlebothrombosis. Of the nonobstructive lesions, only varicose veins occur commonly. These are often the sequelae of the inflammatory reaction and obstruction of thrombophlebitis.

The following classification of the organic diseases of the veins shows their diversity.

### Organic Diseases of the Veins*

A. Obstructive
  1. Thrombophlebitis and phlebothrombosis (venous thrombosis)
     a) Local
     b) Primary
     c) Secondary
     (A more detailed classification appears in the section on thrombophlebitis)

Modified from the nomenclature prepared by the Nomenclature Committee of the Section for the Study of the Peripheral Circulation, the American Heart Association, 1941.

2 Neoplastic invasion of vein

3 Venous compression (with or without thrombosis or thrombophlebitis) due to gravid uterus neoplasm aneurysm, scar tissue, fractures and dislocations, shoulder neurovascular syndromes, increased intraabdominal pressure and extrinsic pressure due to tight girdles, circular elastic garters poorly fitted trusses *etc*

B Nonobstructive

1 Varicose veins
   a) Primary—congenitally incompetent valves
   b) Secondary to obstructive lesions or pressure
   c) Secondary to phlebitic destruction of valves
   d) Compensatory dilatation of collateral veins

2 Arteriovenous fistula—congenital traumatic, mycotic secondary to local disease

3 Aberrant position

4 Hypoplasia

5 *Phlebectasia*

6 Periphlebitis without thrombosis

7 Phlebosclerosis (not usually obstructive)

8 Rupture

## THROMBOPHLEBITIS

### (Phlebitis Phlebothrombosis Venous Thrombosis)

Thrombophlebitis is partial or complete occlusion of a vein by a thrombus associated with an antecedent or secondary inflammatory reaction in the wall of the vein ' Phlebitis ' is generally used synonymously in the literature although the term implies an inflammatory reaction without thrombosis

*Phlebothrombosis* has been popularized as a term by Ochsner and DeBakey and others to indicate a process in which the thrombosis is paramount and the inflammatory reaction mild or absent The thrombosis is due primarily to venous stasis and to those alterations in the cellular and fluid constituents of the blood which increase the clotting tendency *The distinction between* thrombophlebitis and *phlebothrombosis* is this in thrombophlebitis the clot is usually firmly attached to the wall of the vein and is unlikely to become detached in phlebothrombosis, the coagulum is poorly attached and may readily be broken loose to become an embolus The distinction, however is often difficult to make clinically, and clinically and pathologically, the result of the two is frequently the same Furthermore, embolism as the result of a fragment torn loose from the unattached tail of the thrombus in thrombophlebitis is not at all uncommon

*Etiology* —Thrombophlebitis often occurs immediately or shortly after a mechanical injury or as a complication of an acute illness In many cases, however, the condition arises without apparent reason The view held at present is that unexplained thrombophlebitis may occur as a consequence of one or more of the following initial lesions (1) a primary lesion in the wall of the vein involves the endothelium and gives rise to both inflammatory changes in the wall of the vein and to thrombosis within the lumen (2) thrombosis is primary and the result of venous stasis and other blood flow abnormalities that permit the platelets to adhere to the endothelium (3) thrombosis occurs as a result of alterations in the physicochemical properties of the blood that determine its coagulability In (2) and (3) the inflammatory reaction in the wall of the vein is secondary

THE ETIOLOGY OF THROMBOPHLEBITIS

I LOCAL THROMBOPHLEBITIS Changes in wall of vein are primary

A Chemical thrombophlebitis
   1 Result of injection of sclerosing solutions in treatment of varicose veins
   2 Result of injection intravenously of various drugs and diagnostic agents uch as the arsenicals antibiotic hypertonic solutions etc

B Local mechanical injury
   1 Secondary to contusions lacerations and fractures
   2 Axillary thrombophlebitis caused by strain or effort

C Local inflammatory thrombophlebitis (le ion essentially a part of a more extensive inflammatory process) as in erythema nodo um tuberculosis gummas granulomata and miscellaneous inflammations

1 Epidermophytosis (?) (probably by producing cracks in the skin which admit secondary invading organisms)

D *Suppurative thrombophlebitis*

1 Involvement of the wall of the vein by a suppurative process usually due to staphylococci streptococci or pneumococci

E Thrombophlebitis in varicose veins

1 Apparently spontaneous
2 Complicating infectious diseases
3 Postoperatively and post-partum

F Ischemic thrombophlebitis

1 Complicating acute arterial occlusion
2 Complicating *severe chronic occlusive* arterial disease

II Secondary Thrombophlebitis Thrombosis is secondary to underlying disease appears to be primary

A Post-partum thrombophlebitis

1 Milk leg (Phlegmasia alba dolens *puerperarum*)
2 Suppurative thrombophlebitis with pyemia

B Postoperative thrombophlebitis

C *Thrombophlebitis as a late complication* of severe injury

D Thrombophlebitis complicating infectious diseases

E Thrombophlebitis complicating blood dyscrasias such as chlorosis myelogenous and lymphatic leukemia polycythemia vera and anemia

F Thrombophlebitis complicating pregnancy

G Thrombophlebitis complicating noninfectious disease

1 Carcinoma especially visceral such as carcinoma of the pancreas of the lung and of the brain
2 *Heart disease*
  a Congestive heart failure
3 Diabetes *mellitus*
4 Gout
5 *Urinary lithiasis*

H Thrombophlebitis secondary to stasis due to

1 Prolonged dependency of limbs
2 Wearing constricting garments

III Primary Thrombophlebitis No evidence of predisposing systemic or local disease

A *Recurrent idiopathic thrombophlebitis* (thrombophlebitis migrans)

B Nonrecurrent idiopathic thrombophlebitis (essential thrombophlebitis)

## Pathology and Pathologic Physiology

*Pathology* —Although thrombosis and an inflammatory reaction in the wall of the vein *are common to all types of thrombophlebitis* the character of the thrombus and the extent of the phlebitis vary considerably *from case to case*

*The Thrombus* —A venous thrombus may be of three types (1) a red or coagulation thrombus *more or less homogeneous* and resembling a post mortem clot in which platelets and leukocytes are scattered rather evenly through a gelatinous mass of erythrocytes and fibrin (2) a white or agglutination thrombus in which the platelets and leukocytes are distributed in a laminated manner through the fibrin deposit in which very few erythrocytes appear (3) a mixed thrombus the commonest the head of which is white thrombus and the tail red thrombus or (more commonly) alternately red and white thrombus

A white thrombus is formed when venous stasis the development of eddy currents and perhaps a disturbance in the stability of the circulating blood platelets cause the platelets to migrate to the sluggish peripheral portion of the blood stream and become attached to the endothelial lining of the vein

This kind of thrombus is not solid the lamina extending in all directions divide and subdivide to form a honeycombed structure within the lumen The slowly moving blood stream is thus divided into numerous smaller streams In each of these the peripheral flow is slower than in the central *flow* hence more and more *platelets* and leukocytes are deposited on the existing lamina of the thrombus and further obstruct *and subdivide the blood stream* When the vein is completely or almost completely occluded there is sufficient obstruction to *produce* stasis of all or part of the stream A coagulation thrombus then forms proximal to the initial white thrombus Since occlusion *is not always complete* and interference with the venous flow is apt to be intermittent the tail of the thrombus frequently *consists of alternate sections of red thrombus* and white thrombus

A red thrombus alone forms when the *blood flow through a segment of a vessel* is brought to a sudden halt or marked venous stasis is combined with serious alterations

in the physicochemical properties of the blood that control coagulation

Where the injury or inflammation involving the endothelium is localized, the thrombus is also localized initially. Propagation of the tail of the thrombus may cause it to extend unattached, far into the proximal normal segment of vessel. A fragment may be detached and swept from the systemic venous circulation through the right side of the heart into the pulmonary circulation where it lodges as a pulmonary embolus

ring. In other instances, recanalization produces multiple small venous channels pursuing a tortuous and interconnecting course through a fibrous cord. When the valves of the veins are involved they are always damaged or destroyed

The inflammatory reaction in the wall of the vein varies in degree and in extent. It may be so slight as to involve no more than three layers of the wall, but the perivascular tissues as well (*periphlebitis*). During the early stages of thrombophlebitis *there is an infiltration by inflammatory cells*

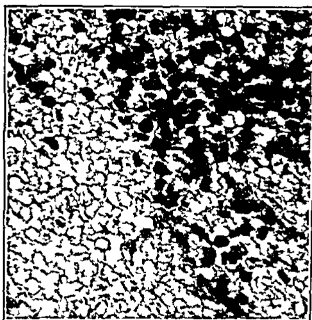

Fig. 181.—Fresh red thrombus composed entirely of erythrocytes. The hemolyzed erythrocytes are unstained. Photomicrograph. (Bell, Textbook of Pathology.)

Detachment of a portion of the tail is more common than detachment of the entire thrombus, especially if the tail has propagated as far as the junction of the involved vein and another large vein

Organization of the attached portion of a thrombus begins promptly with the growth of fibroblasts from the vessel wall into the thrombus. The organization progresses from the margin toward the center of the thrombus. In very large thrombi there is partial fibrosis and partial liquefaction. In some instances the result is the reestablishment of a *single* lumen, reduced in cross section and surrounded by a thick fibrous

leukocytes, lymphocytes and in increasing numbers fibroblasts

There is considerable variation in the pathological picture presented by the various types of thrombophlebitis. In chemical thrombophlebitis the thrombus tends to be adherent over a wide area and its organization is complete. The result is a cord-like fibrotic structure with a minimum of recanalization. Spontaneous thrombophlebitis in varicose veins is often almost purely a red thrombus which undergoes a protracted period of organization and involution. In suppurative thrombophlebitis the intense inflammatory reaction predominates. Col

lections of leukocytes and bacteria in the stroma become abscesses and these may communicate with the blood stream and so produce pyemia

In thrombophlebitis secondary to blood dyscrasias carcinoma and heart failure the inflammatory reaction is often minimal and it appears that the tendency to intravascular clotting in these instances is due largely to alterations in the coagulation mechanism of the blood and to venous stasis In primary idiopathic thrombophlebitis and in the thrombophlebitis secondary to thromboangiitis obliterans the lesions tend to be segmental and to involve the small and medium sized veins The inflammatory reaction is violent and is usually accompanied by considerable periphlebitis

The fibroblastic response is intense and is associated with endothelial proliferation which dominates the pathological picture occlusion appears to be due more to this than to thrombosis Giant cells may participate in the later stages of the reaction The usual result is obliteration of the vein which persists as a cord like structure Rarely is the lumen restored

There is great variation in the degree of the inflammatory reaction which occurs in secondary thrombophlebitis especially that which occurs postoperatively It is difficult to determine whether the thrombosis or the inflammation of the vein is the primary lesion The general view is that stasis and alterations in the coagulability of the blood are important factors in the production of this type of thrombosis

*Pathologic Physiology* —The essential physiological disturbance brought about by thrombophlebitis is obstruction of the venous flow in the involved vessels The degree of interference and its significance depends upon the size and the location of the involved veins and the extent of the thrombosis If only small superficial veins are involved the prognosis is good because of the rich collateral circulation and the numerous anastomoses present in most of the tissues of the body When major vessels are involved such as the iliofemoral or axillary veins obstruction by an extensive thrombus produces a marked rise in venous pressure in the distal portion of the affected limb

This causes intense congestion of the venules and capillaries and leads to transudation and edema There is disagreement about whether obstruction of the perivenous lymphatics plays any role in the early stages of edema formation Persistent chronic edema is probably due in part to such blockage which may persist because of perivascular fibrosis even after the venous channels have been restored by means of recanalization and the activation of collateral pathways

Vasospasm may contribute to venous obstruction during the acute stages of thrombophlebitis such vasospasm is analogous to the segmental arterial spasm that occurs in acute arterial occlusion

The obstructive process results in dilatation of collateral veins these are often overextended and owing to their relatively weak valves and walls tend to become varicosed Venous insufficiency results increased venous pressure producing further dilatation of the vessels and increasing stagnation When the important saphenous valve at the femoral vein is made incompetent in this way the entire venous pressure of the femoral and vena caval system is reversed and brought to bear on the relatively weak saphenous vein The orthostatic factor is very important in the pathologic physiology of the iliofemoral vein

SIGNS AND SYMPTOMS

1 *Pain* —The pain of thrombophlebitis may be slight as when a small segment of a superficial vein is involved or extremely severe as where a large venous trunk is involved It is sometimes local soreness or aching In iliofemoral thrombophlebitis it may be referred to the lumbosacral region and may simulate psoas abscess or spinal disease In patients with migratory thrombophlebitis the same type of local pain may involve venous branches throughout the body Periphlebitis produces relatively severe pain in thrombophlebitis effects of thrombosis are apt to overshadow the pain Pain in the calf produced by forced dorsiflexion of the foot (Homans sign) is sugges-

in the physicochemical properties of the blood that control coagulation

Where the injury or inflammation involving the endothelium is localized, the thrombus is also localized initially. Propagation of the tail of the thrombus may cause it to extend unattached far into the proximal normal segment of vessel. A fragment may be detached and swept from the systemic venous circulation through the right side of the heart into the pulmonary circulation, where it lodges as a pulmonary embolus.

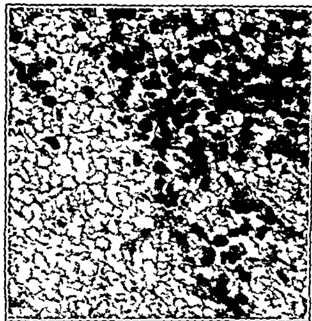

Fig 181 —Fresh red thrombus composed entirely of erythrocytes. The hemolyzed erythrocytes are unstained. Photomicrograph. (Bell, Textbook of Pathology.)

Detachment of a portion of the tail is more common than detachment of the entire *thrombus especially if the tail has* propagated as far as the junction of the involved vein *and another large vein*.

Organization of the attached portion of a thrombus begins promptly with the growth of fibroblasts from the vessel wall into the thrombus. The organization progresses from the margin toward the center of the thrombus. In very large thrombi there is partial fibrosis and partial liquefaction. In some instances the result is the reestablishment of a single lumen reduced in cross section and surrounded by a thick fibrous ring. In other instances recanalization produces multiple small venous channels pursuing a tortuous and interconnecting course through a fibrous cord. When the valves of the veins are involved they are always damaged or destroyed.

The inflammatory reaction in the wall of the vein varies in degree and in extent. It may be so slight as to involve no more than three layers of the wall, but the perivascular tissues as well (*periphlebitis*). During the early stages of thrombophlebitis there is an infiltration by inflammatory cells, leukocytes, lymphocytes and an increasing number of fibroblasts.

There is considerable variation in the pathological picture presented by the various *types of thrombophlebitis*. *In chemical* thrombophlebitis the thrombus tends to be adherent over a wide area and its organization is complete. The result is a cord-like *fibrotic structure with a minimum of recanalization*. Spontaneous thrombophlebitis in varicose veins is often almost purely a red thrombus which undergoes a protracted period of organization and involution. In suppurative thrombophlebitis the intense inflammatory reaction predominates. Col

on bilateral pressure There is usually a brawny swelling of the calf and an unusual prominence of the superficial vessels Pitting edema is not common and there are usually no constitutional symptoms

Any patient in bed after a major operation or a delivery or during a serious illness who complains of pain or tenderness in the calf should be suspected of having thrombophlebitis of the short saphenous muscular, or deep tibial veins

4) *Popliteal and lower femoral veins* Deep tenderness and pain occur along the course of the popliteal and the lower portion of the femoral veins There is usually rise and occasionally chills The temperature of the involved leg is usually unchanged but may be reduced if there is widespread arterial spasm There is tenderness in Scarpa s triangle and the thrombosed vein can be felt here There may be tenderness along Hunter s canal and into the popliteal space

The diagnostic triad for this condition follows diffuse enlargement of the limb congestion of the skin and superficial veins and tenderness in Scarpa s triangle In addition it is very helpful to be able to feel the cord like thrombosed vein

TABLE 55 —THE DIFFERENTIAL DIAGNOSIS OF ACUTE ILIOFEMORAL THROMBOPHLEBITIS ACUTE ARTERIAL OCCLUSION AND ACUTE LYMPHANGITIS WITH CELLULITIS

| | *Acute Iliofemoral Thrombophlebitis* | *Acute Arterial Occlusion* | *Acute Lymphangitis with Cellulitis* |
|---|---|---|---|
| Size of the limb | Enlarged | Unchanged or shrunken | Enlarged |
| Color of the limb | Normal or slightly cyanotic | Pale initially later may be mottled cyanotic | Red |
| Skin temperature of the limb | Usually normal | Low | Elevated |
| Superficial veins | Prominent and distended | Collapsed | Usually unaffected |
| Arterial pulsations | Usually normal | Absent | Normal |
| Chills | Unusual | Absent | Usual at onset |
| Fever | Rarely more than 102 F | Usually absent | Usually high 103 to 104 F |

swelling and congestion of the lower leg Mild constitutional symptoms are common The cord like thrombosed vein can often be palpated

5) *Iliofemoral Thrombophlebitis* The onset is usually sudden but may be preceded by evidence of a more distal thrombophlebitis or by pulmonary embolism The pain is moderate or severe and may extend from above Poupart s ligament down the course of the involved vein to involve the entire leg There is often diffuse pain The superficial veins are somewhat prominent and distended and the skin may be diffusely or locally cyanotic Ordinarily there is significant enlargement of the entire involved extremity Constitutional symptoms are usual fever usually tachycardia and mal

The swelling of the limb is often brawny and firm initially and the skin over the tibia may not then pit on pressure As congestion subsides pitting edema may appear Constitutional symptoms persist for anywhere from a few days to three weeks Before anticoagulant treatment they often lasted for months The tenderness in Scarpa s triangle is ordinarily the last sign to disappear Its disappearance indicates that complete involution has occurred

6) *Axillary brachial or subclavian veins* The picture is much like that presented by iliofemoral thrombophlebitis The thrombosed axillary or brachial vein can readily be felt as a cord There may be intense congestion and considerable cyanosis of the whole arm

tive of thrombophlebitis (phlebothrombosis) of the deep veins of the calf But this is not an infallible test, injuries and inflammations of the muscles and nerves of the calf may cause the pain

2 *Tenderness* —There is usually tenderness along the involved veins, this is diffuse when the deep veins are involved, acute and localized when superficial veins are involved (*e g*, in Scarpa's triangle, Hunter s canal, the popliteal space and in the axilla)

3 *Cramps* —Severe muscular cramps not infrequently occur in cases of phlebitis of deep vessels especially the deep veins of the calf The danger of embolization is increased during the cramps due to the contraction of the muscles upon the thrombosed veins

4 *Color Changes* —Superficial thrombophlebitis is almost always accompanied by redness of the skin over the involved vein This redness may extend either as a red streak along the involved vein or as diffuse patches from the site of involvement With migratory thrombophlebitis such patches appear in each area of involvement As the acute process subsides the patches fade Occasionally, the periphery of an extremity involved by thrombophlebitis becomes blanched or cyanotic this is due to associated vasospasm Gangrene may occur as a result of arterial spasm Pallor may also be prominent in cases of milk leg if lymphatic obstruction is a major factor

5 *Local Swelling* —Mild or moderate local swelling is usually associated with thrombophlebitis When the involved vein is superficial, a lump or a cord like mass is palpable along its course When a deep vein is involved, this lump is often not discovered

6 *Edema* —Thrombosis is accompanied by some degree of congestion throughout the venous system and capillary bed distal to the point of thrombosis There may not be any gross edema This is especially apt to be the cause if the involved vein is superficial and the collateral circulation is adequate But in about half the patients gross edema does occur It is greatest when the large venous trunks especially the femoral iliac, are involved, along with the lymphatic vessels This causes the condition known as phlegmasia alba dolens, or milk leg

7 *Fever* —Fever may or may not be present As a rule there is moderate fever of from 100 to 102° F (from 37 7 to 38 8° C) In rare cases it may be much higher

8 *Tachycardia* —Rapid pulse is common even when there is no fever Persistent tachycardia unexplained on another basis is evidence of continued thrombophlebitic activity

## Laboratory Findings

*Sedimentation Rate* —The sedimentation rate is unpredictable in acute thrombophlebitis, the range is wide but is said to parallel roughly, the degree of fever If the sedimentation rate is high it is probably unwise to permit the patient any activity

*Blood Count* —The leukocyte count may or may not be affected by thrombophlebitis Ordinarily there is no anemia

## Common Sites for Thrombophlebitis

1) *Superficial veins tributaries of the saphenous system, or small cutaneous veins* These vessels are often involved by multiple lesions which appear as red moderately painful and tender raised areas in the skin As a rule the lesions are linear and feel like small cords along the course of the visible vein Constitutional symptoms are rare The inflammatory reaction undergoes involution in from one to three weeks but a firm thrombosed segment of vein can be felt for a much longer period There may be extension to larger vessels

2) *The long and short saphenous veins the median basilic vein and the cephalic vein* Since these veins are large and superficial and are usually involved by periphlebitis the affected vein can ordinarily be felt as a firm cord Edema is uncommon but may occur in the leg if the process is severe and the patient remains ambulatory during the acute stage Constitutional symptoms are usually mild or absent

3) *Muscular veins and deep veins of calf* Thrombophlebitis of the calf veins (phlebothrombosis) causes pain in the calf and tenderness of the calf muscles particularly

to anticipate this complication. Prophylactic therapy, whether pulmonary embolism has occurred or not, includes the institution of anticoagulant therapy.

If a warning embolus is present, heparin and Dicumarol* should be administered immediately; otherwise it is enough to give Dicumarol* alone. New anticoagulants including Tromexan, Paritol and Phenyl-indandione are being studied at present.*

Ligation of the femoral vein for femoral thrombophlebitis, of the iliac vessels or inferior vena cava for iliofemoral thrombophlebitis, and of the long saphenous vein for thrombophlebitis involving this vein are not ordinarily desirable. Venous ligation as a prophylaxis against pulmonary embolism is inferior to anticoagulant therapy because:

(1) acute thrombophlebitis is less apt to produce pulmonary embolism than is phlebothrombosis of the deep vessels; (2) fatal pulmonary emboli arise from sites not recognized during life and therefore not likely to be selected for ligation; (3) venous ligation does not always prevent pulmonary embolism, which may arise from a point proximal to the ligation; (4) anticoagulant therapy is a more effective means of preventing pulmonary embolism. Even if ligation is performed, it should be followed by the administration of anticoagulants.

Ligation of the iliac veins or inferior vena cava is indicated in rare instances, as when thrombophlebitis progresses rapidly despite anticoagulant therapy, when blood dyscrasias tending towards hemorrhage exist, or when there are bleeding or ulcerated mucous membranes. Venous ligation may also be indicated when there is serious liver or kidney disease, or following multiple pulmonary emboli arising from phlebitis in the leg. Lastly, ligation may be used when properly controlled anticoagulant therapy is not available.

*Treatment of Pulmonary Embolism.*—Treatment for small pulmonary emboli includes anticoagulant therapy, the administration of opiates to control pleural pain, and rest in bed until all symptoms and signs have subsided (ordinarily a matter of a week). Anticoagulants should be continued for 3 or 4 weeks after the embolic episode.

Large emboli, such as those producing acute cor pulmonale and shock, call at once for emergency measures. The patient is placed in an oxygen tent and given 50 mg. of heparin, 30 mg. of papaverine and 0.6 mg. of atropine sulfate intravenously. Heparin is continued until Dicumarol* has been given long enough to obtain therapeutic prolongation of the prothrombin time. The patient is kept warm, pain is controlled by codeine or morphine, and papaverine is given every four hours until the acute phase has subsided. The patient is kept in bed until all signs and symptoms have subsided, but anticoagulant therapy is continued for from 3 to 4 weeks.

Shock is combatted by all appropriate means, including blood transfusion, which should be delayed until heparin has been administered. Regardless of the dose of heparin already given, an additional 50 mg. should be given immediately after the transfusion.

*Prevention of Sequellae.*—To avoid the development of chronic venous insufficiency, the patient with moderate-to-severe thrombophlebitis of the leg should not be permitted out of bed until fitted with a knee-length elastic stocking to be worn while he is ambulatory. This stocking should be fitted when the leg is free from edema. It is applied to the leg before the patient leaves his bed and is worn during the entire day; it may be removed when the patient is able to rest in bed with his leg elevated. For the sake of comfort, it may be removed once or twice a day for a short time. After a period of from three to six months, the elastic support may be discarded for half a day to see whether edema appears.

If it does, the stocking is worn for another month, after which the leg is tested again. When the patient can remain ambulatory for half a day without the elastic support and without developing edema, he may try to go a whole day without the support. The stocking may be discarded only when no edema or feeling of heaviness appears in its absence.

* The administration of pellets of heparin by sublingual route is effective; it is an easy and practical way to administer this anticoagulant (Proc. Soc. Exp. Biol. and Med., June 1951).—Editor.

TREATMENT

*Prophylactic.*—Prophylaxis depends on successful management of predisposing diseases, prevention of trauma and venous stasis, and maintenance of normal hemostasis. One attack of thrombophlebitis is likely to lead to other attacks. Thrombophlebitis secondary to thromboangiitis obliterans, a blood dyscrasia or an infectious disease is less apt to occur when the primary disease is controlled. In the presence of congestive heart failure, venous stasis and hypercoagulability of the blood, anticoagulant therapy reduces the risk of venous thrombosis.

Preventive measures for debilitated patients or patients bedridden as a result of major surgery, instrumental or complicated deliveries, or serious illness should include (1) frequent deep breathing exercises, (2) passive and active exercises of the feet and legs, (3) massage of the legs, (4) adequate hydration, (5) adequate treatment of infection, (6) early ambulation, (7) maintenance of optimal environmental temperature, and when the risk of venous thrombosis is great, (8) anticoagulant therapy. Additional measures in surgical, obstetrical and accident cases should include (1) meticulous surgical technique, (2) avoidance of pressure on legs during and after surgery, (3) avoidance of excessive abdominal and inguinal compression from dressings, and (4) maximum care in intravenous therapy (to avoid excessive injury and the infiltration of surrounding tissues).

Venous thrombosis after prolonged dependency and immobilization of the legs during travel by plane, train, bus or automobile can be avoided by periodic exercises and by not wearing circular garters or other constricting garments (*e. g.*, girdles).

*Active.*—The legs of bedridden patients should be examined daily for signs of thrombophlebitis. Early therapy is imperative if phlebothrombosis, which may present the most innocuous local effects but result in pulmonary embolism, is to be controlled promptly.

Rest, heat, elevation and the use of anticoagulants are fundamental in the treatment of thrombophlebitis. Localized superficial thrombophlebitis will ordinarily respond promptly to elevation of the leg or arm and the application of warm, moist packs to it. The packs should extend the full length of the leg or arm and be applied for 20 hours out of each 24 until all tenderness has disappeared, usually in 5 to 10 days.

Instructions for applying packs: Anoint the skin with protective oil or grease and cover with a single layer of gauze. Dip pieces of flannel or turkish towels in boiling water, wring nearly dry, and apply to the entire limb. Be careful not to burn the skin. Wrap a rubber cloth around the flannel and a heavy bath towel around the rubber cloth. Hot-water bottles may be applied outside the bath towel. Moist heat is more effective than dry heat and is less apt to burn the skin.

Pain may be controlled by the use of sedatives or opiates. In 3 or 4 days the patient can usually move the affected leg or arm comfortably. He should then exercise his toes and feet and shift his position frequently. Until the inflammation has subsided, more vigorous motion will cause distress. When pain, tenderness and swelling have subsided and the patient's temperature has been normal for 24 hours, the packs may be discontinued and the patient gradually allowed to become ambulatory. This will ordinarily require from 7 to 14 days. In instances of axillary or subclavian thrombophlebitis the treatment is the same, but the patient may sit in a chair after the first 4 or 5 days if the affected limb can be kept elevated.

Lumbar sympathetic block is indicated when thrombophlebitis is accompanied by marked vasospasm. Ordinarily, moderate vasospasm will respond to heat, elevation, rest, and sedatives or analgesics. In cases of severe vasospasm, sympathetic blocks should be performed on each of the first 2 or 3 days.

*Prevention of Pulmonary Embolism.*—Pulmonary embolism is theoretically more apt to result from phlebothrombosis of the deep veins of the plantar region or the calf than from acute thrombophlebitis. But fatal pulmonary emboli may result from inflammatory thrombophlebitis at any time, and it is beyond the ability of the physician

especially when the long saphenous system is involved The venous flow may actually be reversed so that the blood flows away from the heart through this system (retrograde flow) and from the deep veins through the communicating veins into the long saphenous vein Pooling of blood in the peripheral venous channels causes edema anoxia, and accumulation of metabolic wastes and results in local tissue damage

### Symptoms

The symptoms arising from varicose veins are more often due to chronic venous insufficiency and stasis than to the veins themselves

Extensive varicose veins may, in themselves produce few symptoms Some patients with minimal varicosities may on the other hand present numerous complaints When symptoms appear out of proportion to the extent of the varicosities and the degree of venous insufficiency, other causes for the complaints must be sought—*e g* arterial insufficiency, sciatic pain chronic foot strain fibrositis arthritis, chronic nervous exhaustion or psychoneurosis Frequently moderate or even sharp pain may occur while a varicosity is developing

The most common symptoms are fatiguability of the leg muscles a sense of fullness and congestion in the leg soreness in the region of the varicosities muscular cramps (especially nocturnal) and paresthesias (burning pain and itching) Localized eczematoid dermatitis may develop and lead to pigmentation especially if there has been injury to the skin through scratching Women often complain of the appearance of the varicosities and may have subjective complaints out of proportion to the degree and extent of the venous involvement

### Signs

A complete physical examination should be made of patients with varicose veins treatment depends on the presence or absence of constitutional disease infection peripheral arterial disease abdominal tumor or edema and chronic venous insufficiency which may have resulted from old thrombophlebitis Examination of the veins should be made while the patient is standing on a platform and facing a good light Palpation is often of greater value than inspection

The following tests are used for testing the competency of the saphenous veins

*Brodie Trendelenberg Test* —Blood is drained from the superficial veins of the patient s leg by having the patient lie down and raise his leg The upper portion of the saphenous vein is then obstructed with the fingers and the patient asked to stand Rapid filling while pressure is maintained indicates valve incompetency of the communicating veins As the pressure of the fingers is lifted, rapid filling from above indicates valve incompetency of the saphenous vein Slow filling from below both while pressure is exerted and when it is released is normal

*Perthes Test* —The long saphenous vein is compressed by a tourniquet on the thigh and the patient made to walk briskly Normally the return venous flow is aided by the walking the flow being from the superficial to the deep veins Normally, too the veins disappear rather rapidly thus indicating competent communicating veins If the veins do not disappear, the communicating veins are incompetent, if the veins become more prominent and discomfort or pain occur upon walking, the communicating veins are incompetent and the deep veins obstructed

*The Bandage Test* —The leg is wrapped from toe to knee with a heavy rubber bandage tight enough to compress the superficial veins but not so tight as to interfere with the arterial blood flow

The patient should be comfortable while recumbent He is then asked to walk briskly for 30 minutes If he can do so without discomfort the deep veins are patent Pain on walking indicates obstruction of the deep venous channels and a need to preserve the superficial veins It should be remembered that arterial insufficiency may cause pain under these conditions and should therefore be ruled out before the test is performed

### Diagnosis

The diagnosis of varicose veins is ordinarily not difficult Since varicosities

During the first 4 to 8 weeks after thrombophlebitis, the patient should sleep at night with the foot of his bed elevated 8 or 10 inches. Later, he should exercise his leg regularly by means of bicycle exercises in bed and by swimming. Prolonged rest in bed after thrombophlebitis is inadvisable because of the danger of muscular atrophy and osteoporosis and in apprehensive patients neurosis. When the acute process has subsided, these may be prevented by gentle passive and active exercise in bed and by early ambulation. Post-phlebitic neuritis, while uncommon, may be managed by the single or repeated block of the involved nerve with novocaine. Active motion of the leg and an encouraging attitude on the part of the physician are important in preventing or ameliorating these complications.

## VARICOSE VEINS

(Phlebectasia, Venous Aneurysm)

Varicose veins are simply dilated veins. The term may be used to describe all dilated veins except those which are dilated as a result of arteriovenous fistula or as a part of a vascular tumor.

### Etiology

Primary varicose veins develop spontaneously, presumably as the result of a hereditary weakness of the walls and/or the valves of the veins. Because of this weakness, the veins are unable to withstand the increased pressure which results from such factors as orthostatism (prolonged standing), increased abdominal or pelvic pressure (abdominal obesity, pregnancy, large intra-abdominal tumors), or external pressure (constricting garters and girdles).

Secondary varicose veins are ordinarily a late complication of thrombophlebitis, most commonly iliofemoral thrombophlebitis. The thrombophlebitic process damages and destroys the walls of the vein and the valves not only of the involved vein but of the communicating veins between the deep and superficial systems as well. Secondary varicose veins may develop in the absence of hereditary predisposition to varicose veins if the venous pressure is increased significantly by obstruction.

The frequent appearance of varicose veins in women during pregnancy is explained largely on the basis of an increase in the venous pressure in the legs. The mechanism for the increased pressure is presumed to be a combination of the following factors: pressure of the uterus on the iliac veins, increased intra-abdominal pressure, and increased venous blood flow from the internal iliac veins into the common iliac vein.

### Incidence

Varicose veins are exceedingly common among the general population. They occur at all ages and with considerable frequency after the age of twenty, more commonly in women than in men.

### Pathology

The essential pathological changes in varicose veins are (1) dilatation of the veins, (2) elongation and increased tortuosity, (3) fibrosis and loss of elasticity, (4) irregular thickening (usual) or thinning (unusual) of the walls of the veins as a result of muscular hypertrophy and subintimal and interstitial fibrosis, and (5) atrophy and destruction of the valves.

Incompetency of the valves is believed to be largely secondary to the dilatation of the vein; the valves, however, may be involved in the destructive inflammatory process leading to dilatation. At any rate, dilatation of the veins leads to valvular incompetence, which, in turn, predisposes to further progressive dilatation of the involved vessels.

Varicosities occur most commonly in saphenous veins and their tributaries. The communicating veins between the superficial and deep systems are frequently involved. Involvement of the superficial cutaneous veins is very common. The deep veins are less often involved.

The venous pressure is usually but not always elevated in varicosed veins. This pressure is elevated dramatically even in normal veins of the legs when a person changes from the recumbent to the erect position. More important than the venous pressure is the marked change in blood flow

appear until orthostatism has added its burden to the pressure on the tissues. As it progresses *the edema is complicated by cyanosis, congestion, pigmentation and sometimes purpura and petechiae.*

*Dermatitis or eczema commonly occur.* The eczema may be dry and scaling or moist and weeping. Intense pruritis may lead to persistent scratching.

The longer the edema exists, the greater *is the subcutaneous fibrosis.* Eventually the swelling does not disappear upon recumbency. Often a low grade inflammatory process supervenes, leading to chronic indurative cellulitis. The patient is then prone to develop all the serious complications *inherent in this type of lesion: lymphangitis, erysipelas,* ulceration.

Ulceration is common and serious in chronic venous insufficiency. It develops where the nutrition of the skin is most impaired, particularly where trauma has increased the local insult. It may occur anywhere at the site of chronic induration *or eczema, most commonly in the region of* the ankles, above and below the malleoli. Ulcers may be of any size and shape and tend to become chronic if the patient remains

TABLE 56.—THE DIFFERENTIAL DIAGNOSIS OF CHRONIC VENOUS INSUFFICIENCY

| *Condition* | *Features Which Differentiate Condition from Chronic Venous Insufficiency* |
|---|---|
| | I. CONDITIONS PRODUCING SWELLING OF THE LEG |
| *Congestive Heart Failure* | Edema is usually *bilateral and symmetrical,* often present elsewhere. *Is* usually accompanied by other evidence of heart failure |
| *Chronic Nephritis (Nephrotic Syndrome)* | *Edema is soft, pale, pitting, bilateral, symmetrical and occurs elsewhere.* Urinary findings and history clarify diagnosis |
| *Chronic Lymphedema* | *More diffuse induration without venous congestion or dilated veins.* Edema is pale. Subsides slowly if at all upon recumbency and elevation. No dis*tension and dilatation of superficial venules* |
| Arteriovenous Fistula | History of penetrating injury or presence since birth. Presence of thrill and *bruit not invariable. Increased length of limb and dilated veins in unusual* locations and distribution. Oxygen saturation of venous blood is increased |
| | II. CONDITIONS PRODUCING PAIN IN THE LEG |
| Intermittent Claudication (Muscle Ischemia) | Pain develops only during muscular activity, is relieved by rest without elevation. Evidence of arterial insufficiency |
| Tumors of the deep structures of the leg | Uncommon. Usually in upper calf. *Irregular structure.* Bone tumors differentiated on x-ray |
| Abscesses | Uncommon. Site may be unrelated to vein. Signs of acute inflammatory process |
| *Myositis* | Uncommon. *Absence of superficial induration and cutaneous changes.* Absence of venous disease |
| | III. CONDITIONS PRODUCING INDURATION OF LEG |
| Scleroderma | Commonly involves digits. Absence of venous disease. May present peripheral arterial disease. Upper extremity more commonly involved |
| Tumors | Uncommon, *see above* |
| Acute Cellulitis | Acute onset and evidence of acute inflammatory process. Etiology other than venous insufficiency |
| | IV. CONDITIONS PRODUCING ULCERATION OF LEG |
| Hypertensive-Ischemic leg ulcers | Long standing or severe hypertension. Commonly peripheral arterial disease. Absence of venous disease. Very rare |
| Syphilitic ulcers | Tend to form on upper portion of leg, to be multiple and to form a pattern. Begin as nodules, ulcerate and heal with atrophic scars. Serological tests helpful |
| *Arterial insufficiency* | Most common on toes and feet. *Usually painful.* If on leg, usually follow trauma. Other signs of arterial insufficiency but not those of venous insufficiency |
| Ulcerative tuberculids | Usually bilateral and symmetrical. May occur elsewhere. *Painful nodules which ulcerate and resist therapy* |

not uncommonly follow obstruction of the veins proximally, such obstructions should be sought and removed, if possible. Occasionally, varicose veins arise secondary to arteriovenous fistula; this may be suspected when varicosities have existed from birth or have followed trauma, particularly penetrating injury.

### Complications

The complications of varicose veins are thrombophlebitis and chronic venous insufficiency. Chronic venous insufficiency is manifested by cyanosis, edema, acute or chronic induration and cellulitis, necrosis, ulceration, eczema, and pigmentation of the skin.

### Treatment

*Conservative Treatment.*—The conservative management of varicose veins is indicated for patients with early, mild varicosities and for those in whom more active therapy is contraindicated. The measures employed are (1) adequate periods of rest with the feet and legs elevated; (2) avoidance of unnecessary standing and walking; (3) avoidance of external constrictions about the legs and hips (girdles, garters, *etc.*); (4) support of the legs by elastic bandages or stockings. This type of management is useful for many cases, especially during pregnancy.

*Injection Treatment.*—Injection treatment may be done alone or in combination with surgical ligation or extirpation of the veins. Satisfactory results are obtained by injection alone only when performed on small superficial varices (telangiectatic spider bursts) or on localized varices not associated with any general incompetency of the saphenous systems.

The results of injection therapy for large varicose veins are usually disappointing, the varices tending to recur within a year or two.

*Surgical Treatment.*—The techniques of venous ligation, of retrograde injection and of excision of veins are beyond the scope of this discussion. Severe varicosities associated with incompetency of the great or small saphenous systems must be treated surgically if permanent improvement is sought. The procedure usually consists of dividing the greater saphenous vein at the saphenofemoral junction and either injecting the distal segment of the vein immediately with sclerosing solution or excising the vein through multiple small cutaneous incisions.

In patients with severe varicosities in the short saphenous system, this vein may be ligated and divided in the popliteal space. Small and localized residual varicosities remaining after operation may be obliterated by injection. It is often necessary to ligate individually the bulging superficial ends of the communicating veins to produce a satisfactory result.

## CHRONIC VENOUS INSUFFICIENCY

(Venous Stasis, Stasis Edema, Stasis Eczema, Stasis Ulcer, Varicose Ulcer, Postphlebitic Ulcer.)

Chronic venous insufficiency is a localized or generalized pathological state of the tissues, usually of the legs, resulting from stasis of the venous blood flow. Stasis is usually caused by obstruction of a venous trunk, particularly the iliofemoral. The obstruction results from thrombophlebitis, neoplastic invasion, continued extrinsic pressure, incompetence of the valves of the iliofemoral vein through destruction by thrombophlebitis or old and extensive varicosities.

In venous stasis the venous blood is deficient in oxygen and contains an excess of carbon dioxide and protein metabolites. Increased venous pressure and slowing of the venous stream result in abnormal function of the venules and capillaries. Failure of the reabsorption mechanism leads to edema. A vicious cycle is set up which manifests itself in fibrosis, induration, cellulitis, pigmentation, necrosis and ulceration. These changes result from pressure, congestion and poor nutrition.

### Symptoms and Signs

The first manifestation of chronic venous insufficiency is subcutaneous edema which responds to bed rest. Other signs do not

mount importance is control of the edema If, on fair trial ambulant therapy does not bring about healing of stasis ulcer the patient must be put to bed

After a stasis ulcer heals, the patient must wear an elastic support for a long time, often for a year sometimes permanently Areas of ulceration on which pressure is not exerted by an elastic support must be covered with a sponge or molded latex pad beneath the elastic bandage or stocking Ulceration is apt to recur if venous stasis is not controlled and trauma prevented

## HYPERTENSIVE-ISCHEMIC LEG ULCERS

Otherwise unexplained ulcers on the leg may be the so-called hypertensive-ischemic leg ulcers well described by Hines and Farber in 1946 In some cases of hypertension the arterioles of the skin become occluded and small areas of skin are infarcted When these infarcted areas break down an ulcer is formed Most hypertensive-ischemic ulcers described in the literature have been in the region of the ankle

Clinically, a painful red plaque appears, becomes cyanotic and then purpuric The small area of discoloration develops into a hemorrhagic bleb which breaks down to form a superficial ulcer The ulcer enlarges slowly to reach a size of from 1 to 7 cm Healing is protracted, since granulations form slowly and there is only slight exudation Pain is often quite severe

Pathologically there is thickening of the walls of the cutaneous arterioles and a proliferation of the intima which narrows the lumen There is hyperplasia of the media with hyaline degeneration and a perivascular reaction

## CRANIAL ARTERITIS

### (Temporal Arteritis)

Cranial arteritis is a febrile self limited inflammatory disease of variable duration and unknown etiology involving the temporal and often other arteries of the cranial system It chiefly occurs in persons over fifty

### Etiology

The character of this debilitating but subacute condition suggests that it may be due to a low grade infection Indeed focal infection has been suggested as the cause extraction of the teeth having resulted in improvement in a few cases Attempts to explain the disease on an allergic basis have also been made but these are scarcely convincing for the disease is highly localized, eosinophilia is not ordinarily a feature, and the patients are almost always elderly Though the lesions of cranial arteritis may sometimes resemble those of periarteritis nodosa pathologically the two conditions are so different in clinical course that it seems impossible that they should be closely related

### Pathology

The larger temporal arteries become tortuous nodular, and swollen Pulsations may be present or they may be absent as a result of nodulation or thrombosis There may be cellulitis of the surrounding tissues Facial carotid occipital cerebral and retinal arteries may be involved Microscopically panarteritis with hypertrophy of the intima necrosis of the media and granulomatous changes (often showing giant cells) in the vascular walls may be observed Externally periarterial cellular infiltration of the affected vessels occurs internally thrombosis is common Eosinophilic lesions rarely occur

### Symptoms and Signs

*Cerebral symptoms* include headache vertigo nausea vomiting mental sluggishness and confusion delirium and rarely coma *Ocular symptoms* include photophobia various degrees of blindness ptosis and retinal changes *Systemic symptoms* usually severe include fever, malaise, anorexia weight loss sweating and weakness *Local signs* depend on the degree of inflammation and induration Pulsations in the temporal arteries are abolished when thrombosis occurs or when diffuse induration or nodulation are advanced Periarterial cellulitis may supervene

ambulatory. We have seen ulcers of more than 35 years' duration. Infection is common. Ulcers do not ordinarily occur on the upper leg or on the feet.

Pain is produced by a variety of causes in chronic venous insufficiency. On walking there is a dull ache, due to the stasis and congestion; this pain is usually relieved by recumbency and elevation of the leg. Arthritic pains are often aggravated in a leg with chronic venous insufficiency. Nocturnal musclar cramps may occur from venous insufficiency. Pain due to ulcers and indurative cellulitis may be severe though usually relieved by rest and elevation. Neuritis of the nerves supplying the long saphenous vein and other tissues occasionally occurs.

## Treatment

The patient with chronic venous insufficiency should stay in bed with the affected leg elevated until all edema has disappeared and should be made to wear an elastic stocking or bandage before leaving bed. This support, which the patient should wear at all times while he is ambulatory, should extend from toe to knee, but not above the knee. Even though equipped with such a support, the patient should avoid unnecessary walking or standing. The foot of his bed should be elevated at least 6 inches from the floor at night so that the veins and tissue spaces of the affected leg will tend to drain. Superficial varicose veins should be ligated, injected, or both, if the deep veins are competent.

Epidermophytosis should be treated by soaking in 1:5000 to 1:10 000 potassium-permanganate solution once or twice daily for 30 minutes. Fungicidal dusting power may also be used, but strong fungicides should not be used on devitalized tissues.

Eczema will improve as stasis is overcome, but symptomatic measures are necessary for pruritis. If an elastic support cannot be tolerated because of itching, pain or oozing, the patient should be kept in bed. Local measures for subjective relief include the application of 3 per cent ichthyol in zinc-oxide ointment, wet dressings of 0.5 per cent aluminum subacetate, or 0.01 per cent potassium permanganate. A satisfactory antipruritic is 10 per cent ethyl aminobenzoate ointment (benzocaine, anesthesin).

Cellulitis requires bed rest, elevation of the limb, and the application of warm, moist dressings. If the condition is spreading or producing a systemic reaction, antibiotic or chemotherapeutic treatment is indicated. If the cellulitis is chronic and advanced, improvement may take several weeks.

Purpura and petechial hemorrhages due to capillary rupture are secondary to increased venous pressure and local nutritional deficiency. The addition of 300 mg. of vitamin C to the daily diet of patients so afflicted is desirable.

The presence of stasis ulcer calls for bed rest and elevation of the limb until edema has subsided. If clean, the ulcers are exposed to the air; if infected, they are treated with wet dressings of penicillin or tyrothricin. Local varicosities should be ligated promptly, if possible, to prevent the retrograde blood flow which often prevents healing of the ulcer. The skin around the ulcer should be protected with a bland and soothing ointment. Healing of bacteriologically clean ulcers appears to be accelerated in some cases by the daily application of dried human erythrocytes (Lyocyte powder).

When edema has subsided, compression may be applied to the area of ulceration by binding on sterile rubber sponges, or applying elastoplast bandages, or even an Unna paste boot. The healing of clean ulcers is accelerated by the application of split thickness skin grafts.

Since many patients with ulcers cannot or will not stay in bed long enough for the ulcer to heal, proper management of the condition on an ambulatory basis is important. If possible, the patient should be kept in bed until edema has subsided.

For the ambulatory patient, the ulcer is cleansed and covered with sterile Vaseline gauze. Pressure is exerted over the area by the application of a piece of sponge rubber somewhat larger than the ulcer. This is held in place with a piece of elastoplast bandage. Elastic support to the leg is provided by means of an elastic bandage or stocking or an Unna paste boot. Of para-

lymph system are lymphatic fistula, chylous ascites due to obstruction of the thoracic duct, and obstruction due to fibrosis and calcification.

## LYMPHEDEMA

Lymphedema is a swelling of the soft tissues which is due to an increased quantity of lymph in the tissue spaces. The term *elephantiasis* implies an enormous swelling of the legs without indicating the cause. A simple and convenient classification of the causes of lymphedema follows:

ETIOLOGICAL CLASSIFICATION OF LYMPHEDEMA (OBSTRUCTIVE NON-INFLAMMATORY DISEASE OF THE PERIPHERAL LYMPH VESSELS)

1. *Primary lymphedema*
   - a. Congenital (simple) lymphedema
   - b. Hereditary lymphedema (Milroy's disease)
   - c. Lymphedema praecox
2. Secondary lymphedema due to
   - a. Surgical removal of lymph nodes
   - b. Neoplastic invasion of lymph nodes
   - c. X-ray treatment

### ETIOLOGY

The mechanism of lymphedema is always the same regardless of the primary cause. Obstruction of the lymph flow by inflammatory or non-inflammatory processes causes stasis, increases lymph pressure, and produces dilatation of the vessels. Dilatation of the vessels produces insufficiency of the valves and so eliminates one of the two important factors assisting the flow of lymph. Obstruction furthermore causes the lymph to seek other channels than those normally used. The protein content of the lymph increases; fibroblastic proliferation then leads to fibrosis and further stasis. An increase in protein-rich extracellular fluid predisposes to attacks of acute inflammation which in turn produce thrombosis of the lymphatics, further lymph stasis, and further fibrosis.

### INCIDENCE

Primary lymphedema occurs chiefly among women and usually during the second or the third decade of life. The involvement is unilateral in about 70 per cent of the cases. The congenital form is evident at birth or soon afterwards. Milroy's disease is the familial form. The secondary forms of lymphedema are relatively uncommon.

### PATHOLOGY

The characteristic pathological picture of congenital lymphedema includes thickening of the subcutaneous tissues and replacement of the adipose tissue with enlarged lymph spaces and connective tissue. There are no thromboses of lymphatics or blood vessels and no inflammatory changes.

Other types of lymphedema are characterized by thickening of the skin and subcutaneous tissues (with replacement of the adipose tissue by lymph channels and connective tissue), atrophy of muscles, nerves, and sweat glands, and infiltration of the tissues by lymphocytes, leukocytes, and other cells.

### CLINICAL SIGNS

*Lymphedema Praecox.*—This type of lymphedema occurs spontaneously, usually at puberty or during adolescence. The first sign is a slight puffiness around the foot or ankle. This is frequently more pronounced during long periods of activity, during menstruation, and in warm weather.

Rest in bed with elevation of the limb produces temporary disappearance of the edema. One or both limbs may be involved, or one may be involved months after the appearance of the edema in the other limb. The edema may progress up the leg either rapidly or slowly. In a few cases the swelling does not progress beyond the ankle or beyond the knee.

The edema becomes progressively more severe and, though reduced through rest and elevation, reappears upon activity and dependency. The skin becomes roughened and the edema more resistant to pressure. Hypertrophy of the soft tissue results in a large, uncomfortable, and unsightly limb. The patient may feel a sense of heaviness in the limb, but pain does not occur. Inflammatory reactions are uncommon and ulceration does not occur. Since only the lower limbs are involved, gravity is thought

### Course

The onset is usually insidious, the patient may suffer constitutional disturbances for weeks or months before the focal symptoms appear. There are usually fever, sweating and vague generalized aching. Progressive weight loss may be dramatic. Headache develops, usually over the involved vessels. Pain may radiate to the occiput, the jaw, the sides of the head, or to the face. Pain may limit the movement of the jaws and interfere with eating.

The cervical lymph nodes may be enlarged and tender. The involved arteries usually become red and thick. Nodules or induration may be felt. Pulsations may be lost.

TABLE 97.—DIFFERENTIAL DIAGNOSIS BETWEEN CRANIAL ARTERITIS AND PERIARTERITIS NODOSA (ESSENTIAL POLYARTERITIS)

| | *Cranial Arteritis* | *Periarteritis Nodosa* |
|---|---|---|
| Age of Patients | Usually 50 years or older | Any age from infancy on |
| Distribution of Lesions | Localized always to the temporal arteries and associated cranial arteries | May involve any artery in the body and usually is generalized. May involve various arteries progressively. May involve veins |
| Eosinophilia | Rare | Occurs in about 20 per cent of cases |
| Prognosis | Good. Never fatal. May lead to blindness | Poor. Usually fatal |

Visual disturbances may appear—photophobia, diplopia and in a number of cases blindness. Constitutional and local symptoms may persist for months or even years.

### Laboratory Findings

There is usually but not always a polymorphonuclear leukocytosis. Eosinophilia is characteristically absent. The sedimentation rate is ordinarily elevated, sometimes tremendously. There may be a mild anemia. The urine is normal, and the results of the Wassermann test are negative. An increased protein content of the cerebrospinal fluid has been reported.

### Diagnosis

The differential diagnosis between cranial arteritis and the disseminated forms of arteritis is usually apparent.

### Treatment

Cases of cranial arteritis may exhibit complete remission of symptoms without treatment. Excision of the involved arteries often but not always relieves the pain. The fever will often continue after the excision. When excision fails to produce relief, deeply situated arteries are probably involved. Roberts and Askey have reported that the periarterial injection of the temporal arteries with procaine hydrochloride (1–2 cc.) brings marked and lasting relief when these arteries alone are involved. Analgesics and sedatives are only partly effective. The use of opiates is to be avoided.

## DISEASES OF THE PERIPHERAL LYMPH VESSELS

The lymph vessels are closed vessels, very similar to the veins in structure. They have valves and an unbroken endothelial lining and are in contact externally with the tissue spaces. Every main blood vessel has an accompanying lymph vessel. Most parts of the body are richly supplied with lymph vessels and in many regions, including the limbs, these are arranged in two systems—the superficial and the deep. The course of each lymph vessel is interrupted by lymph nodes through which the lymph passes on its way toward the systemic circulation. Lymph, the fluid contained in these vessels, contains prothrombin and fibrinogen but is relatively deficient in thromboplastic substance. It clots, therefore, less rapidly than does blood. The pressure of lymph is low and its circulation largely depends on the action of the skeletal muscles aided by the action of the valves in the lymph vessels.

The two common abnormal conditions of the peripheral lymphatics are noninflammatory lymphedema and inflammatory lymphangitis. Both are obstructive conditions. Uncommon abnormalities of the

sistent lymphedema leads to progressive fibrosis, which will not respond to anything less than surgical extirpation. Early lymphedema is not unlike the edema of varicose veins in that there are dilated lymph vessels with incompetent valves and stasis of the circulating fluid. Medical treatment is designed to support the lymph vessels and prevent stasis and the effusion of fluid into the tissue spaces. This is accomplished by compression of the limb with an elastic support.

Before a compression bandage or stocking is fitted to the lymphedematous leg, all possible edema must be removed by putting the patient to bed and elevating the involved limb in a sling. When the size of the limb is reduced satisfactorily, an elastic stocking is fitted to the limb. Non-elastic bandages are useless and elastic bandages are undesirable because they are difficult to apply, tend to slip and curl, and do not exert pressure evenly over the entire leg. Elastic stockings have the disadvantages that they require expert fitting, lose their elasticity after repeated washings, and are expensive. The only criterion is whether the support prevents edema.

The bandage is applied over a lisle stocking—two turns about the foot, two figure-eight turns about the ankle, and so on up to the knee. Experience will teach the patient how to apply the bandage.

The patient puts on the elastic support each morning before getting out of bed and wears it constantly while ambulatory. A midday rest with the leg elevated and the elastic support removed is desirable. Extra elastic supports should be available to permit frequent washing.

*In cases with advanced fibrosis* the wearing of a support may be permanent. In early cases there may be retardation of the lymphedematous process in six months or a year. The rule is to wear a support as long as necessary. Even when the edema has disappeared, a support should be worn during periods of prolonged standing or walking.

The treatment of secondary lymphedema of the arm is based on similar principles. W. T. Foley has devised an elastic half glove and sleeve which has been useful in managing these cases.

*Surgical Treatment.*—Surgical intervention is indicated only in instances of advanced or extensive lymphedema. In milder cases the radical procedures are out of proportion to the deformity produced by the lymphedema and do not assure that the lymphedematous process will not continue.

The most popular procedure has been the Kondoleon operation, in which the skin of three-quarters of the circumference of the extremity is undermined and the fascial sheath of the muscle is completely removed. This permits the superficial lymph to drain through the muscular lymphatics. A recent technique involves the subcutaneous insertion of threads to encourage the drainage of lymph around sites of obstruction.

## LYMPHANGITIS

### (Inflammatory Lymphedema)

Lymphedema of inflammatory origin is the result of single or recurrent attacks of acute cellulitis and lymphangitis. Primary lymphangitis, the more common form, occurs abruptly as a result of bacterial infection, ordinarily streptococcic, although the portal of entry is usually obscure. Secondary lymphangitis arises from local injuries or infections, trichophytosis, systemic infections or infestations, and filariasis. The following classification is based on etiological considerations.

Etiological Classification of Lymphangitis (Inflammatory Lymphedema)

1. Primary lymphangitis (cause unknown)
2. Secondary lymphangitis due to
   a. Filariasis
   b. Trichophytosis
   c. Local tissue injury or inflammation (lacerations, bites, burns, furuncles, other local infections, chemical, non-bacterial)
3. Erysipelas

### Cellulitis and Lymphangitis

The acute attack of cellulitis and lymphangitis is ushered in by a shaking chill, sometimes preceded by a brief period of discomfort in the involved extremity or its proximal lymph nodes. The patient's

to play an important part in the production of the condition

*Congenital Lymphedema* —Congenital lymphedema may be non hereditary or hereditary (Milroy's disease) In simple congenital lymphedema there is a diffuse swelling involving part or all of a single extremity at birth As growth occurs, the size of the involved extremity continues to be greater than that of the uninvolved limb The swelling is firm, pits on pressure and is reduced by prolonged elevation There is no pain nor do ulceration or inflammation occur The length of the extremity is not greater than that of the opposite limb nor is the temperature of the limb elevated above that of the companion limb as in congenital arteriovenous fistula

*Secondary Lymphedema* —This type of lymphedema arises from occlusion of lymph vessels by metastatic malignancies or lymphoblastomas, from obliteration of the lymph channels by surgical removal of the lymph nodes, or from post irradiation therapy There may be intercurrent attacks of lymphangitis or cellulitis

Lymphedema secondary to filariasis is common in areas where this infestation is endemic but rare in the United States Filariasis is discussed in the section on Nematode infections (Chapter 8)

TABLE 58 —THE DIFFERENTIAL DIAGNOSIS OF LYMPHEDEMA

| *Condition* | *Differential Features* |
|---|---|
| | I SYSTEMIC DISEASES |
| Congestive Heart Failure Myxedema Nephritis Nephrosis Hypoproteinemia | There is no difficulty in distinguishing unilateral lymphedema from the bilateral edema of systemic disease Careful and complete examination is necessary when lymphedema is bilateral |
| | II VASCULAR DISEASES OF THE LIMB |
| Arteriovenous Fistula | In *A–V* fistula there is enlargement of the limb increased pressure in and dilatation of the regional veins venous oxygen content approaching that of the arteries *If A–V fistula is congenital or acquired early in life* the limb is increased in length as well as in circumference Limb is warmer than its opposite |
| Chronic Venous Insufficiency | |
| Early | Differentiation is often difficult Venous insufficiency may be apparent from mode of onset rapidity of onset and progress amount of distress to the patient and dilatation of superficial veins The two conditions exist together rarely |
| Late | Edema of venous insufficiency is softer and is accompanied by dermatitis stasis ulcers and superficial varices Lymphedema does not lead to eczematoid dermatitis ulceration or superficial varicosities |
| | III OTHER CONDITIONS IN THE LIMB |
| Lipodystrophy | Lipodystrophy is bilateral and is usually associated with generalized obesity or obesity around the waist and hips It does not extend although it may become more pronounced There is less pitting in lipodystrophy Lipodystrophy is never accompanied by cellulitis and lymphangitis Bed rest and elevation of the limb have little influence on lipodystrophy |
| Malignant and Benign Tumors | These are unilateral Edema is localized or regionalized Lymphosarcoma produces extensive edema of lymphatic origin but the regional lymph nodes are enlarged Roentgen examination and biopsy will assist in the diagnosis |
| *Angioneurotic Edema* | Characteristically cyclic in character |
| Neurofibromatosis | Nodular enlargements and neurofibromata elsewhere |

TREATMENT

*Medical Treatment* —Treatment of lymphedema must be instituted at once Per

temperature rises rapidly to 101 to 105° F (38 3 to 40 5° C ) An area of rubor appears at the site of the inflammation and spreads rapidly The involved area is hot tender, and swollen The regional lymph nodes become swollen and tender The temperature remains elevated for some hours and chills recur at intervals There is marked malaise and there may be nausea and vomiting The ordinary attack subsides in a few days, but the recession of the signs of acute inflammation may be followed by a persistent degree of edema When attacks are recurrent, each attack leaves a greater degree of residual edema There may be some permanent discoloration of the skin In all types of inflammatory lymphedema, the attacks of acute lymphangitis are accompanied by thrombosis of the lymph channels This thrombosis produces the obstruction and stasis which contributes to the progressive edema formation

## Treatment

Acute lymphangitis is always a serious condition Its prevention is important but, in many cases there are no premonitory signs Active treatment includes putting the patient to bed elevating the affected limb, and applying moist hot packs from toe to groin when the leg is involved and from the fingers to the axilla when the arm is involved Antibiotics should be administered freely A search should be made for a primary portal of entry, which may be a superficial abrasion, an interdigital fissure or a chronic leg ulcer Acute lymphangitis is particularly hazardous when it involves a limb rendered relatively ischemic by obliterative vascular disease

Local treatment includes the elimination of factors which favor infection eradication of infected epidermophytosis removal of eschars over infected wounds or ulcers, incision and drainage of abscesses Recurrent lymphangitis complicating another peripheral vascular condition will usually fail to respond until the underlying disease is controlled

# Chapter 25

# Diseases of the Blood

By CYRUS C. STURGIS, M.D.

## INTRODUCTION

The circulating blood is a suspension of erythrocytes, leukocytes and platelets in liquid plasma. The main function of the red blood cells by virtue of their hemoglobin is the transportation of oxygen from the lungs to the tissues; that of the leukocytes chiefly the defense of the body against infection, and that of the platelets the coagulation of blood.

The normal blood values of an adult male weighing 70 kilograms are as follows:

| | |
|---|---|
| Total blood volume (80 c.c. per kilo) | 5600 c.c. |
| Average red blood cells per cubic millimeter | 5.4 million |
| Total number of red blood cells in body | 3 trillion |
| Average duration of life of red blood cell | 120 days |
| Number of red blood cells replaced daily in body | 25 billion |
| Hemoglobin content of blood per 100 cc. | 15.6 grams |
| Total hemoglobin in body | 859 grams |
| Amount of iron in hemoglobin | 0.334 per cent |
| Amount of iron in total hemoglobin of circulating blood | 2.877 grams |

### Normal Hematologic Standards and Some Diagnostic Measures Employed in Examination of the Blood

Important data on the volume of the red blood cells and their hemoglobin content are obtained by calculations based on the red blood cell count, the hemoglobin determination, and the estimation of the volume of packed red blood cells by means of the hematocrit.

The more important values are:

(1) Mean Corpuscular Volume (cubic microns)

$$\frac{\text{Vol. Packed Red Blood Cells, c.c. per 1000 c.c.}}{\text{R.B.C. millions per cu. mm.}}$$

(2) Mean Corpuscular Hemoglobin Concentration (%) (M.C.H.C.)

$$\frac{\text{Hb. Grams per 100 c.c.} \times 100}{\text{Vol. Packed Red Blood Cells, c.c. per 100 c.c.}}$$

(3) Mean Corpuscular Hemoglobin (Micromicrograms) (M.C.H.)

$$\frac{\text{Hb. in Grams per 1000 c.c.}}{\text{R.B.C. Millions per cu. mm.}}$$

(4) *Color Index*

$$\frac{\text{Hb. in Grams per 100 c.c.} \times 6.4}{\text{R.B.C. in millions per cu. mm.} \times 20}$$

The following table shows the normal hematological standards collected by Dr. Frank H. Bethell and used at the Simpson Memorial Institute of the University of Michigan.

TABLE 59

| | Men | | Women | |
|---|---|---|---|---|
| | *Range** | *Average* | *Range** | *Average* |
| Number of red blood cells per cu mm | 4 70– 6 00 | 5 35 | 4 13– 5 21 | 4 67 |
| Hemoglobin grams per 100 c c | 13 39–17 63 | 15 51 | 12 17–15 01 | 13 59 |
| Packed Cell Volume (hematocrit) per cent | 41 36–52 88 | 47 12 | 37 66–45 44 | 41 60 |
| Mean Corpuscular Hemoglobin micromicrograms | 26 08–32 00 | 29 04 | 26 34–32 02 | 29 13 |
| Mean Corpuscular Hemoglobin Concentration, per cent | 30 21–35 62 | 32 92 | 30 12–35 08 | 32 60 |
| Mean Corpuscular Volume, cubic microns | 81 26–95 26 | 88 26 | 82 17–96 85 | 89 51 |
| Color Index | 0 90– 1 10 | 1 00 | 0 90– 1 10 | 1 00 |
| Volume Index | 0 91– 1 07 | 1 00 | 0 92– 1 09 | 1 00 |
| Saturation Index | 0 92– 1 09 | 1 00 | 0 92– 1 07 | 1 00 |

* The ranges include 95 per cent of all observations on normal subjects and are derived from data which have been shown to be statistically significant

TABLE 60

| *Type of Anemia* | *M C V cu microns* | *M C Hb C per cent* | *Color Index* |
|---|---|---|---|
| Macrocytic normochromic | 96–160 | 30–35 | 1 0 |
| Normocytic normochromic | 82–96 | 30–35 | 1 0 |
| Microcytic hypochromic | 50–92 | 21–29 | 0 5–0 9 |

By utilizing the mean corpuscular volume and the mean corpuscular hemoglobin concentration it is possible to recognize the different types of anemia based on the volume of the red blood cells and their hemoglobin content The three most important with one example of each are as follows (1) macrocytic normochromic anemia (Addisonian pernicious anemia) (2) normocytic normochromic anemia (the anemia of infection), (3) microcytic hypochromic (iron deficiency anemia)

Table 60 gives the average findings for each of the three different types of anemia

## WHITE BLOOD CELLS

These cells numbering from 5000 to 10,000 per cubic millimeter in the peripheral blood have as their chief function the defense against infection in the body When their number falls below 5000 per cubic millimeter a *leukopenia* is said to be present when the number is above 10,000 per cubic millimeter there is a *leukocytosis* These cells are characterized by (1) a relatively short life, 2 to 3 days, (2) the power of motility which permits at least some of them to engulf microorganisms and to migrate from the blood stream into the tissues and (3) the presence of digestive enzymes The percentages of the various types of leukocytes are as follows Neutrophils, band 3–6%, lobed 55–57% total 58–67%, eosinophils 1–3% basophils 0–1% lymphocytes 20–30% monocytes 5–9%

The conditions commonly associated with a neutrophilia are (1) acute infections especially with staphylococci and streptococci (2) intoxications as uremia and acidosis (3) hemolysis (4) severe acute hemorrhage (following operations especially those involving the abdominal cavity) malignancy, and myelogenous leukemia

Causes of a leukopenia are (1) infections especially those due to a virus such as influenza and measles (2) an overwhelming infection of any type (3) diseases of the blood forming organs as pernicious anemia

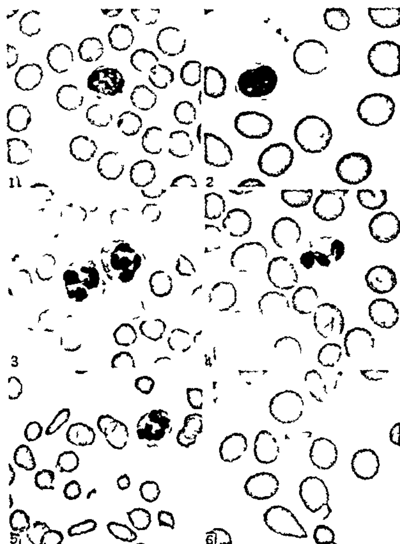

Fig 181 —Variation in the shape and size of the erythrocyte (photomicrographs × 1100) 1 Normal red cells Note the uniform diameter and central depression 2 Macrocytes in pernicious anemia The cells are large and filled with hemoglobin 3 Microcytes in hypochromic anemia The cells are quite small and very pale due to the low hemoglobin content 4 The flattened cell of chronic obstructive jaundice The volume of the cells is normal but the diameter is uniformly increased so the thickness is less than normal 5 The red cells in idiopathic hypochromic anemia These show marked microcytosis hypochromia and anisocytosis The elongated cells are quite characteristic of this condition 6 Poikilocytosis in pernicious anemia The oval and pear shaped cells are commonly seen in pernicious anemia (Haden s Principles of Hematology)

aplastic anemia acute and subleukemic leukemias and primary splenic neutropenia (4) agranulocytosis usually due to drugs and (5) Banti s Felty s and Gaucher s disease

A lymphocytosis may be present in infancy and childhood and in (1) certain infections as pertussis rubella infectious lymphocytosis and infectious mononucleosis (2) lymphatic reactions to infectious disease in childhood (3) tuberculosis with good resistance (4) exophthalmic goiter and (5) lymphatic leukemia A lymphopenia may be seen in (1) advanced Hodgkin s disease (2) excessive irradiation (3) agranulocytosis (4) leukemia other than lymphatic (5) tuberculosis with poor resistance (6) infections with increase in neutrophils

A monocytosis may be observed in (1) chronic pyogenic infections (2) protozoal infections as malaria (3) subacute bacterial endocarditis (4) typhus and Rocky Mountain spotted fever, (5) in some cases of Hodgkin s disease (6) tuberculosis with poor resistance (7) monocytic leukemia

An eosinophilia may be associated with the following conditions (1) parasitic infestations (2) allergic conditions (3) skin diseases (4) disseminated vascular disease (5) pernicious anemia treated with liver diet

A basophilia may be seen (1) in association with an increase in the eosinophils and (2) in chronic myelogenous leukemia

## Incidence of Blood Diseases

Evidence accumulated in the past decade indicates that anemia is perhaps more common than previously suspected For example in about 25,000 routine admissions of patients over 14 years of age in the in patient and out patient departments of the University of Michigan Hospital an anemia of clinical significance was found in one out of every 8 persons (12 per cent) Of these the most frequently observed (41 per cent) was a normocytic normochromic type usually due to a chronic infection and less commonly to chronic nephritis Next in frequency (39 per cent) was a microcytic hypochromic anemia resulting from an iron deficiency which is usually secondary to chronic hemorrhage The remaining group included patients with myelophthisic anemia in association with various conditions as leukemia Hodgkin s disease and different types of cancer the macrocytic anemias such as pernicious anemia refractory anemias and the hemolytic anemias

It is of interest to note that in a routine study of a group of normal pregnant women it was found that 54 per cent had an anemia more severe than the physiologic anemia of pregnancy, and of these the largest proportion had an anemia of the iron deficiency type In recent years, certain anemias as for example the sickle cell variety have been recognized as occurring with greater frequency among Negroes and Mediterranean anemia occurring usually in persons of Greek or Italian ancestry, is not so rare in the United States as previously supposed

There is convincing evidence to show that leukemia is observed more often than it has been This is due in part to better diagnostic methods As the increase is in all age groups however, it cannot be attributed to the fact that more persons live longer than middle age Pernicious anemia is observed more commonly now than it was fifty years ago partly because diagnostic methods are more accurate and partly because more persons live to the age at which the disease most commonly occurs

## The Mechanisms of the Production of the Anemias

An anemia may be defined as a diminution in the concentration of hemoglobin or erythrocytes or both below the standards accepted as normal for age and sex Such a condition may arise as a result of deficient formation or increased destruction of blood or a combination of the two In health the number of formed elements of the peripheral blood the erythrocytes the leukocytes and the platelets are maintained at a constant level with great exactness In the case of the erythrocytes and probably also the leukocytes and platelets this is possible because in any given period of time just as many red blood cells are delivered from the bone marrow to the circulation as are destroyed

If blood is lost by hemorrhage failure of the marrow to produce red blood cells at a normal rate or abnormal destruction of red blood cells the delicate balance which maintains the blood at a constant level is upset and an anemia results Aplastic anemia with actual destruction of the bone marrow as the result of poisoning (as for example with benzol) is an excellent example of an anemia due to decreased blood formation An anemia which probably results solely from increased destruction of red blood cells is chronic hemolytic anemia of the congenital type In this condition it is possible to demonstrate that the red blood cells are more fragile than normal this explains at least in part why they are so readily destroyed

A great majority of anemias arise primarily on account of deficient blood formation due either to an inability to synthesize hemoglobin normally or to a slowing up of the rate of red blood cell maturation. *Hemoglobin* is formed in the body from heme which is derived from glycine and acetic acid acting in combination with globin and iron. This process occurs in the red blood cells of the bone marrow, chiefly at the normoblast and reticulocyte stages over a period of several days. Ordinarily there is no lack of globin or heme in the body, but a common cause of anemia is a deficiency of iron, without which hemoglobin cannot be formed. With lack of this metal there is a deficiency of hemoglobin and a microcytic hypochromic anemia results. The inability to synthesize hemoglobin normally probably also accounts for the development of another common type of anemia, namely, the anemia *of infection*. Although all the factors which control the rate of formation of the erythrocytes are not known, it is recognized *that pteroylglutamic acid (folic acid) and the* recently discovered vitamin $B_{12}$ play important roles in the regulation of this process. For example, in nutritional anemia there is probably a deficiency of folic acid and in Addisonian pernicious anemia one of vitamin $B_{12}$, a deficiency that results in a retarded rate of development of the red blood cells in the bone marrow. Consequently, as blood destruction proceeds at a normal (or perhaps an accelerated) rate, an anemia of the macrocytic type must result. Decreased blood production is shown by an absence or sparsity of immature forms of red blood cells such as reticulocytes, nucleated erythrocytes, and cells showing polychromatophilia.

Anemia due to increased destruction of red blood cells (hemolytic anemia) is less common than anemia due to decreased blood formation. Evidences of increased destruction are hyperbilirubinemia, fever and frequently a palpable spleen. With an increase in the amount of bilirubin in the plasma there develops an icteric tint in the skin and conjunctivae which is apparent in the various hemolytic anemias. As bilirubin is derived from hemoglobin, it has been assumed that the amount present in the plasma is a rough index of the extent of *blood destruction. While this is undoubtedly* true in some instances, in certain anemias such as pernicious anemia it must be admitted that an excess of bilirubin in the plasma may mean nothing more than a failure to use all of this available material in the formation of red blood cells.

It is interesting to note that all three formed elements of the blood are subject to alterations in numbers, there being either an increase or decrease in various diseases. For example, the red cells are diminished in the anemias and increased in polycythemia. The white blood cells are increased in the leukemias and decreased in agranulocytic angina. The platelets are diminished in some types of purpura and increased following *hemorrhage, after splenectomy,* and sometimes in the chronic leukemias. In most diseases of the blood, although the pre*dominating change is in the number of any* one of the three formed elements, there is almost always an associated change in the *other two.*

## SYMPTOMS AND SIGNS IN DISEASES OF THE BLOOD

In diseases of the blood there are symptoms and signs which are due to various changes, such as enlarged lymph glands, splenomegaly and hepatomegaly, and to the development of the commonly associated anemia of varying degree. The latter is often the more important. Symptoms due to the anemia may result from (1) rapid loss of blood, a loss that manifests itself chiefly by evidences of shock; (2) rapid destruction of blood, such a condition as is seen in acute hemolytic crises (common causes of jaundice and fever in the hemolytic anemias); and (3) the anemia *per se*, a condition that produces manifestations in direct proportion to the level of the hemoglobin of the circulating blood.

When the hemoglobin falls to the vicinity of 11 grams (70 per cent), the symptoms of anemia usually become apparent, and as the hemoglobin falls they become more severe. Evidences of an anemia are pallor, weakness, ease of fatigue, dyspnea, palpitation, vertigo, fainting attacks and sometimes edema of

the ankles *Pallor* as observed in the face is not always indicative of anemia, for the color of a person s skin is not entirely dependent on the hemoglobin level in the blood It is also concerned with the distribution and size of the skin capillaries, natural pigmentation sunburn, artificial coloring and excessive fatigue Recently developing and persistent pallor, however, is likely to be indicative of the presence of an anemia Usually the anemia can be detected more accurately by observing the mucous membranes or the palms of the hands

*Dyspnea* and *palpitation* on exertion are almost invariably associated with anemia, although rarely do these manifestations appear when the patient is at rest These complaints are due to the diminished capacity of the blood to carry oxygen to the tissues When exertion demands an increase in oxygen, the amount of air breathed and the circulatory rate are increased with the consequent production of these symptoms

*Weakness* and *ease of fatigue* are the most constant complaints associated with anemia and may be of such extreme grade as to confine the patient to bed These complaints are associated with the inability of the cardiovascular apparatus to deliver sufficient oxygen to the tissues for the necessary combustion incident to muscular exertion

*Edema of the ankles* is not infrequently observed in the severe anemias but its cause is not always apparent That it is closely associated with the anemia is suggested by its disappearance when the blood returns to normal although some time may elapse before this occurs In some instances it undoubtedly results from a poor appetite and a suboptimal intake of protein with the consequent development of low plasma proteins and an associated decreased osmotic pressure, in other patients it may be due to an associated myocardial weakness or to changes in the blood capillary walls following nutritional disturbances which make them more permeable to fluid

*Vertigo* and *faintness* are considered to be due to an anoxia of the brain

IMPORTANCE OF AN ACCURATE DIAGNOSIS

An accurate diagnosis is absolutely essential in the management of various blood diseases If the anemia is detected by demonstration of a low hemoglobin, and a combination type of therapy instituted in the hope that the patient will improve, some good may be accomplished but this method of therapy invites failure and does not provide an intelligent basis for establishing a prognosis A thorough history and physical examination must be done, along with a complete blood study, including an accurate hematocrit determination, to provide a basis for estimating the cell volume and hemoglobin content Additional studies as roentgen ray examinations, biopsy and sternal puncture may be necessary before the actual diagnosis is established

## IRON DEFICIENCY (MICROCYTIC HYPOCHROMIC) ANEMIA

By CYRUS C STURGIS, M D

*Definition* —An iron deficiency anemia is a commonly occurring microcytic hypochromic variety which results from an inadequate supply of available iron in the body for the formation of a normal amount of hemoglobin Such a deficiency arises from diverse causes such as *chronic hemorrhage*, a *low dietary intake* repeated pregnancies and prolonged lactation rapid growth malabsorption or from any type of infection which may inhibit the utilization of iron salts A

*gratifying response usually follows iron therapy*

*It is now recognized that the nutritional* anemia of infancy and childhood chlorosis *or the hypochromic anemia of adolescent* girls the hypochromic anemia of pregnancy *the hypochromic anemia of chronic blood* loss and the idiopathic' hypochromic *anemia of adult women* are all varieties of the same condition which results from a *decreased supply of available iron in the* body These clinical syndromes have much *in common as they differ only because of the* age and sex of those affected

*Frequency*—These anemias are of the greatest importance because they occur at any age *in either sex and are one of the* most prevalent types observed in clinical *medicine An indication of their great* frequency is obtained from the studies of Davidson Fullerton and Campbell in 1935 in the poor of Scotland They found that such an anemia occurred in 41 per cent of the infants under two years of age 32 per cent of the children of pre-school age 16 per cent of adolescent girls and 45 per cent of adult women A study made at the University of Michigan Hospital several years ago showed that 39 per cent of all patients over 14 years of age admitted to the hospital or seen in the Out Patient Department who had an anemia had the iron-deficiency type

*Etiology*—Since iron is an essential part of the hemoglobin molecule (it is present in a percentage of 0 334) a deficiency in that metal will result in an iron-deficiency anemia A brief survey of iron metabolism is necessary to understand the causes of such a deficiency It is known that the average adult has in his body a total of about 4 2 grams of iron of which at least 55 per cent is in the hemoglobin of the circulating blood On an intake averaging from 10 to 15 milligrams a day one can provide his body with all the iron it needs and accumulate between 600 and 1000 milligrams of iron reserves held principally in the liver and reticulo endothelial system

Iron is taken into the body in the ferric form and acted upon by hydrochloric acid in the gastric juice to make it more soluble and prevent the formation of insoluble iron compounds It then passes into the intes*tine where it is reduced to the ferrous form* and absorbed as such Since iron is excreted *only in the bile and the urine and in amounts* averaging only 1 2 milligrams daily and the *iron intake is much larger it is apparent* that the amount of the metal in the body *must be regulated by an effective control of* its absorption It has been shown in *general that the body will absorb iron ef*ficiently when the reserves are low and reject *it entirely or in part when the reserves are* adequate When absorbed it combines with *apoferritin an iron free protein in the in*testinal wall to form ferritin It is then *distributed throughout the body as plasma* iron combined with globulin ($B_1$) This *protein is able to bind about 300 micro*grams of iron but is normally only about 35 *per cent saturated when iron-deficiency* anemia is present it may be only 10 per cent saturated (Finch)

The causes of iron depletion and iron deficiency anemia are as follows

1 *Loss of Blood*—Acute hemorrhage in an otherwise healthy person is rarely the cause of such an anemia for the iron reserves provide for the formation of from 1200 to 2000 cc of blood Chronic hemorrhage is the chief cause of such an anemia This occurs most commonly when there is a loss daily over long periods of small unnoticed quantities of blood For example a hemorrhage totaling only two teaspoonfuls of blood means the loss of 4 milligrams of iron Chronic hemorrhage is most commonly due to peptic ulcer and cancer of the stomach the large bowel the sigmoid and the rectum Other causes may be epistaxis bleeding from esophageal varices and more rarely bleeding from the small bowel as the result of enteritis benign tumor ulcer and vascular disease In women uterine bleeding is most commonly responsible for such an anemia

Since chronic bleeding is by far the most common cause of iron-deficiency anemia and probably the only single cause that results in such an anemia the rule should be when a microcytic hypochromic anemia is encountered to search at once for the source of blood loss In women despite the fact that they may insist that their menstrual periods are normal a common cause of such anemia is

the ankles *Pallor* as observed in the face is not always indicative of anemia, for the color of a person's skin is not entirely dependent on the hemoglobin level in the blood It is also concerned with the distribution and size of the skin capillaries, natural pigmentation sunburn, artificial coloring, and excessive fatigue Recently developing and persistent pallor however, is likely to be indicative of the presence of an anemia Usually the anemia can be detected more accurately by observing the mucous membranes or the palms of the hands

*Dyspnea* and *palpitation* on exertion are almost invariably associated with anemia, although rarely do these manifestations appear when the patient is at rest These complaints are due to the diminished capacity of the blood to carry oxygen to the tissues When exertion demands an increase in oxygen the amount of air breathed and the circulatory rate are increased with the consequent production of these symptoms

*Weakness* and *ease of fatigue* are the most constant complaints associated with anemia and may be of such extreme grade as to confine the patient to bed These complaints are associated with the inability of the cardiovascular apparatus to deliver sufficient oxygen to the tissues for the necessary combustion incident to muscular exertion

*Edema of the ankles* is not infrequently observed in the severe anemias but its cause is not always apparent That it is closely associated with the anemia is suggested by its disappearance when the blood returns to normal although some time may elapse before this occurs In some instances it undoubtedly results from a poor appetite and a suboptimal intake of protein with the consequent development of low plasma proteins and an associated decreased osmotic pressure in other patients it may be due to an associated myocardial weakness or to changes in the blood capillary walls following nutritional disturbances which make them more permeable to fluid

*Vertigo* and *faintness* are considered to be due to an anoxia of the brain

Importance of an Accurate Diagnosis

An accurate diagnosis is absolutely essential in the management of various blood diseases If the anemia is detected by demonstration of a low hemoglobin, and a combination type of therapy instituted in the hope that the patient will improve, some good may be accomplished, but this method of therapy invites failure and does not provide an intelligent basis for establishing a prognosis A thorough history and physical examination must be done, along with a complete blood study, including an accurate hematocrit determination, to provide a basis for estimating the cell volume and hemoglobin content Additional studies as roentgen ray examinations, biopsy and sternal puncture may be necessary before the actual diagnosis is established

## IRON DEFICIENCY (MICROCYTIC HYPOCHROMIC) ANEMIA

By Cyrus C Sturgis M D

*Definition* —An iron deficiency anemia is a commonly occurring microcytic hypochromic variety which results from an inadequate supply of available iron in the body for the formation of a normal amount of hemoglobin Such a deficiency arises from diverse causes such as chronic hemorrhage a low dietary intake repeated pregnancies and prolonged lactation rapid growth malabsorption or from any type of infection which may inhibit the utilization of iron salts A

between 60 and 70 cubic microns and a Price-Jones curve with a pronounced shift of the peak to the left These findings indicate a hypochromic microcytic anemia which is almost always due to iron deficiency

The white blood cells are usually within normal limits but may be slightly reduced or occasionally be as low as 2000 per c mm Fresh *hemorrhage may produce a leukocytosis* with an increase in the percentage of neutrophils The blood platelets are usually normal but may be reduced in number They too may be increased in acute hemorrhage The recticulocytes are most frequently from 1 to 3 per cent but may be increased to 10 or 12 per cent following acute bleeding

*Bone Marrow* —The marrow is characteristically hyperplastic with a predominance of normoblasts often with a poverty of hemoglobin There is an approximate relationship between the number of these cells and the severity of the anemia Megaloblasts are absent but young normoblasts are not infrequently observed There is no important variation from normal in granulopoiesis Following specific therapy with iron the marrow returns to normal

Marrow preparations unstained or stained with Berlin blue normally show a considerable number of hemosiderin granules In the opinion of some observers (Rath and Finch 1948) this may be used as an index of the amount of iron stored in the tissues In iron-deficiency anemia diminution or absence of these granules may be observed

*Other Laboratory Findings* —The *blood bilirubin* is within normal limits as is the icterus index The *plasma proteins* and the albumin fraction may be reduced and account for edema in some patients This is probably chiefly due to low intake of protein *Achlorhydria* is usually present in the so-called idiopathic hypochromic anemia of women and occasionally in the hypochromic anemia of childhood in chlorosis the acidity is said to be normal or increased

*Iron* in the blood plasma is protein bound to $B_1$ globulin which holds 2 molecules of iron to one of protein In normal persons the total iron binding capacity is 300 gamma per 100 cc of serum but the circulating iron binding protein is only about 34 per cent saturated with iron In patients with iron-deficiency anemia it is usually below 10 per cent saturation (Rath and Finch, 1949)

## VARIOUS TYPES OF IRON-DEFICIENCY ANEMIAS

### Hypochromic Anemia of Infancy and Childhood (*Nutritional Alimentary* Chlorotic Anemia of Infancy)

This commonly occurring type of iron deficiency anemia is due to multiple etiologic factors as follows (1) A maternal iron deficiency which results in an infant being born with a normal hemoglobin of the blood but devoid of the usual iron reserves (2) Premature infants twins or those who for any other reason have a low birth weight may likewise have deficient iron reserves Rapid growth during the first year of life causes an increased demand for iron especially because the hemoglobin content of the body is doubled during this interval (3) A low iron intake due to prolonged artificial feeding exclusively with cow s milk which has a suboptimal iron content (4) Other factors may be infection anorexia achlorhydria or chronic diarrhea which interferes with the normal absorption of iron

This condition may in some instances be prevented by the administration of iron to the mother during pregnancy In the infant it responds promptly to this form of medication

### Chlorosis

*Definition* —An iron-deficiency anemia occurring in adolescent girls This is a disease limited to the adolescent female with the onset occurring usually between the ages of fourteen and seventeen years All evidence indicates that it is identical in every respect with the idiopathic hypochromic anemia of adult women except the age of onset and the presence of a normal amount of hydrochloric acid in the gastric juice Moreover as Richard Cabot said It takes the eye of faith to see the greenish yellow hue which such patients have been said to present in the past The characteristic blood changes are those of a hypochromic microcytic anemia Thayer reported 63 cases with a

profuse menstruation Three or four times the normal amount of menstrual blood may be lost each period without the patient's being aware of it

2 *Diminished Intake of Iron in the Diet* — This alone probably never causes an anemia although it may be an important contributing factor In infants and adolescents at the periods of rapid growth, a diet low in iron may result in such an anemia

3 *Increased demand for iron* due to rapid growth, pregnancy and lactation During periods of rapid growth as in infancy and at puberty and during pregnancy and lactation there is a notable increase in the body s demand for iron, hence it is at these times that iron-deficiency anemias are most likely to occur

4 *Malabsorption of Iron* —The efficiency of the absorption of iron is in part related to the amount of hydrochloric acid in the gastric juice Hydrochloric acid favors absorption achlorhydria has the effect of converting a diet high in iron to one low in iron Chronic diarrhea may also impair absorption

5 *Chronic Infection* —Chronic infection is associated with abnormal iron metabolism This is thought to result from the diversion of plasma iron to the tissues where it is not available for hemoglobin formation In the presence of an infection therefore excessive iron deposits appear to be made in the tissues but a relative iron deficiency seems to exist in the serum and red blood cells (Finch)

When bleeding, alone or in combination with other causes exhausts the iron reserves the body undoubtedly attempts to absorb more iron from the intestinal tract If this fails, the deficiency causes a hypochromic microcytic anemia, characteristic of iron deficiency

It should be reiterated that the most common cause of such an anemia is chronic hemorrhage usually from the gastrointestinal tract or the uterus Dietary deficiency increased demands due to growth pregnancy and lactation malabsorption and infection may play important roles in the etiology Whether any of these other than hemorrhage is the sole cause of such an anemia is doubtful

## Findings Common to All Iron Deficiency Anemias

*Symptoms* —The complaints of patients with an iron-deficiency anemia are similar to those of patients with any other type of anemia and are proportional to the degree of reduction of hemoglobin of the circulating blood Symptoms may be very mild or absent, especially in children but also in adults For example a healthy nurse, on active duty was admitted to the University of Michigan Hospital with a mild upper respiratory infection, and was unexpectedly found to have an iron-deficiency anemia with a hemoglobin of 50 per cent She insisted however that none of the symptoms of anemia were present and that she could work efficiently for eight hours daily without undue fatigue In most instances however definite chronic complaints are present although the patient does not appear acutely ill Ordinarily, the chief symptoms are weakness ease of fatigue pallor dyspnea on exertion palpitation a capricious appetite and vague digestive disturbances Physical examination usually discloses only a moderate loss of weight pallor often a hemic murmur and other features which are given under the heading of various types of iron deficiency anemia The fact that only a few positive findings are discovered on physical examination is important from the standpoint of diagnosis

*Blood Examination* —The most characteristic features are as follows (1) The pronounced decrease in the amount of hemoglobin contained in each red cell as indicated by a greater reduction in it than in the total red blood cell count For example a characteristic finding would be a red blood cell count of 3 500 000 per c mm and the hemoglobin of 35 per cent which gives a color index of 0 5 Other findings in accord with this are a mean corpuscular hemoglobin concentration usually varying from 25 to 30 per cent and a saturation index varying from 0 75 to 0 90 The mean corpuscular hemoglobin is within the limits of from 15 to 21 micromicrograms (2) There is a decrease in the size of the cells as indicated by mean diameter—usually between 6 2 and 6 7 microns mean corpuscular volume—usually

between 60 and 70 cubic microns and a Price-Jones curve with a pronounced shift of the peak to the left. These findings indicate a *hypochromic microcytic anemia* which is almost always due to iron deficiency.

The white blood cells are usually within normal limits but may be slightly reduced or occasionally be as low as 2000 per c mm. Fresh hemorrhage may produce a leukocytosis with an increase in the percentage of neutrophils. The blood platelets are usually normal but may be reduced in number. They too may be increased in acute hemorrhage. The reticulocytes are most frequently from 1 to 3 per cent but may be increased to 10 or 12 per cent following acute bleeding.

*Bone Marrow*.—The marrow is characteristically hyperplastic with a predominance of normoblasts often with a poverty of hemoglobin. There is an approximate relationship between the number of these cells and the severity of the anemia. Megaloblasts are absent but young normoblasts are not infrequently observed. There is no important variation from normal in granulopoiesis. Following specific therapy with iron the marrow returns to normal.

Marrow preparations unstained or stained with Berlin blue normally show a considerable number of hemosiderin granules. In the opinion of some observers (Rath and Finch 1948) this may be used as an index of the amount of iron stored in the tissues. In iron-deficiency anemia diminution or absence of these granules may be observed.

*Other Laboratory Findings*.—The *blood bilirubin* is within normal limits as is the icterus index. The *plasma proteins* and the albumin fraction may be reduced and account for edema in some patients. This is probably chiefly due to low intake of protein. *Achlorhydria* is usually present in the so called idiopathic hypochromic anemia of women and occasionally in the hypochromic anemia of childhood; in chlorosis the acidity is said to be normal or increased.

*Iron* in the blood plasma is protein bound to $B_1$ globulin which holds 2 molecules of iron to one of protein. In normal persons the total iron binding capacity is 300 gamma per 100 cc of serum but the circulating iron binding protein is only about 34 per cent saturated with iron. In patients with *iron-deficiency anemia* it is usually below 10 per cent saturation (Rath and Finch 1949).

## VARIOUS TYPES OF IRON-DEFICIENCY ANEMIAS

### Hypochromic Anemia of Infancy and Childhood (Nutritional, Alimentary, Chlorotic Anemia of Infancy)

This commonly occurring type of iron deficiency anemia is due to multiple etiologic factors as follows: (1) A maternal iron deficiency which results in an infant being born with a normal hemoglobin of the blood but devoid of the usual iron reserves. (2) Premature infants, twins or those who for any other reason have a low birth weight may likewise have deficient iron reserves. Rapid growth during the first year of life causes an increased demand for iron especially because the hemoglobin content of the body is doubled during this interval. (3) A low iron intake due to prolonged artificial feeding exclusively with cow's milk which has a suboptimal iron content. (4) Other factors may be infection, anorexia, achlorhydria or chronic diarrhea which interferes with the normal absorption of iron.

This condition may in some instances be prevented by the administration of iron to the mother during pregnancy. In the infant it responds promptly to this form of medication.

### Chlorosis

*Definition*.—An iron-deficiency anemia occurring in adolescent girls. This is a disease limited to the adolescent female with the onset occurring usually between the ages of fourteen and seventeen years. All evidence indicates that it is identical in every respect with the idiopathic hypochromic anemia of adult women except the age of onset and the presence of a normal amount of hydrochloric acid in the gastric juice. Moreover as Richard Cabot said, "It takes the eye of faith to see the greenish yellow hue" which such patients have been said to present in the past. The characteristic blood changes are those of a hypochromic microcytic anemia. Thayer reported 63 cases with a

red blood cell count averaging about 4 000 000 per c mm and an average hemoglobin of 42 per cent Iron is specific in the condition, although it should be administered over a period of several months, and the patient observed for recurrences

It has been said that chlorosis has disappeared but apparently this is not the case if the above interpretation of the syndrome is accepted It is not unusual to see the mild form but the severe type is rare

### Hypochromic Anemia of Blood Loss

Detailed reference has been made to this syndrome under the heading of Etiology of the Iron-Deficiency Anemias It need only be reiterated here that this is one of the most common varieties of anemia encountered in the United States, and also undoubtedly in other parts of the world The blood findings in chronic blood loss are the typical ones observed in the iron-deficiency anemias and the therapeutic response to iron is prompt and satisfactory, unless the loss of blood is continued and excessive

### Hypochromic Anemia of Pregnancy

Observations have shown that a considerable number of otherwise normal pregnancies are accompanied by an iron deficiency It is unlikely that the gravid woman can retain a sufficient quantity of dietary iron to meet the demands of pregnancy which are occasioned by the added requirements of the fetal and maternal organism Moreover as the hydrochloric acid is diminished in many pregnant women this may result in an impaired absorption Preexisting reserves of iron in the body therefore must be called upon to satisfy the increased needs If these stores are depleted before pregnancy as they frequently are a further diminution will occur during the gravid state which will inevitably result in an iron-deficiency anemia unless suitable preventive or curative measures are instituted A second point to be considered is that the normally present increase in blood volume in pregnancy greatly augments any anemia which may exist as the result of other causes For example, the normal maximum blood dilution, as a result of hydremia, of 26 per cent usually occurs at about the sixth month If the hemoglobin percentage were 70 before the pregnancy, this dilution factor alone would reduce it to approximately 58 per cent

It is advisable that routine studies should be made as a part of prenatal care, and unless the values are unquestionably normal, iron medication should be given promptly and continued throughout gestation

### 'Idiopathic' Hypochromic Anemia

*Synonyms* —Simple achlorhydric anemia Simple achylic anemia Primary hypochromic anemia Chronic microcytic anemia Essential hypochromic anemia

*Definition* —A chronic microcytic, hypochromic anemia almost always occurring in women between the ages of twenty and fifty years who have an absence or reduced amount of free hydrochloric acid in the gastric juice The condition results from an iron deficiency in the body, attributable to diverse causes but chiefly to chronic hemorrhage and responds uniformly and favorably to iron therapy

*Etiology* —This syndrome is almost entirely limited to females although it has been reported occasionally in males According to Wintrobe and Beebe 60 per cent of the affected individuals are between thirty and fifty years of age while 82 per cent are twenty to fifty years These appears to be definite constitutional and hereditary trends in the disease and an ill-defined relationship to pernicious anemia Often there is a family history of anemia and families have been observed in which there have been cases of hypochromic anemia with achlorhydria some of which later changed to pernicious anemia and others which had the characteristics of pernicious anemia from the onset

There are four chief etiologic factors all of which may play a causative role in any given patient They are as follows (1) the most important is bleeding often unnoticed most frequently menorrhagia but also from other sources such as hemorrhoids and epistaxis (2) a deficiency of iron in the

diet (3) malabsorption of iron due to the achlorhydria or hypochlorhydria (4) frequent pregnancies at relatively short intervals

*Symptoms and Physical Examination* —The onset is gradual and the precise time of the initial appearance of symptoms is difficult to determine Usually the patient has been ailing for several years before consulting a physician In some instances the patient has apparently become adjusted to a low hemoglobin in the blood and consequently it may be surprising to find that the complaints are vague and relatively scant The symptoms are usually those associated with any anemia in which asthenia predominates Other complaints are mild chronic indigestion low resistance to respiratory infections emotional instability and vague neurotic pains Menorrhagia is common as on careful questioning it will be found that three-fourths or more of these women have an excessive loss of menstrual blood This is an important aspect of the history which is often overlooked unless particular attention is given to it A certain amount of glossitis and atrophy of the papillae of the tongue are present in about one third of the patients Rarely do these conditions attain the prominence observed in pernicious anemia Numbness and tingling of the extremities may be present but it differs from that of pernicious anemia as only 15 or 20 per cent of the patients have such a complaint and when present it is milder in degree and rarely as persistent When these *patients complain of dysphagia in addition* to the other symptoms the condition is then spoken of as the *Plummer Vinson syndrome*

Physical examination shows a variable degree of pallor either fair nutrition or moderate emaciation and frequently oral sepsis which probably bears no etiologic relationship to the disease In some cases there may be an acute glossitis with a tongue which appears intensely reddened while other patients may have no symptoms referable to the tongue but there may be atrophy of the papillae which gives the dorsum a smoothed-out appearance The finger nails may be dull lusterless and have longitudinal ridges A number of these patients have a peculiar concavity of the finger nails koilonychia ( spoon nails ) which usually affects the nails of several fingers but is most pronounced in the index finger The edge of the liver and the spleen may be palpable in a small number of patients These organs are never grossly enlarged In patients with severe anemia there may be pitting edema of the extremities The heart may be border line in size and a soft systolic apical ( hemic ) murmur is commonly present An important aspect of the physical examination is to exclude other conditions which might cause a similar anemia

*Blood* —The features are the characteristic ones of a microcytic hypochromic anemia In 90 per cent of the cases reported by Wintrobe and Beebe the red cells numbered between 3 000 000 and 5 150 000 per c mm and in 74 per cent the hemoglobin was 6 to 10 grams (38 to 64 per cent on the basis that 15 6 grams = 100 per cent)

*Gastric Analysis* —In about three fourths of the patients there is a failure to secrete hydrochloric acid in the gastric juice following the injection of histamine In the remainder there is almost always a hypochlorhydria

## TREATMENT AND PROGNOSIS OF IRON DEFICIENCY ANEMIAS

*Treatment* —Adequate doses of iron are specific in the iron-deficiency anemias The treatment of choice is ferrous sulphate 0 32 gram (5 grains) three times daily before meals A long trial has convinced me that *the enteric-coated tablets given before meals* will produce satisfactory results in almost all instances If gastrointestinal manifestations arise the preparation may be administered after meals and if necessary the dose reduced to one or two 0 32 gram (5 grain) tablets daily and the patient's tolerance determined Ordinarily a dose of 0 32 gram (5 grains) before meals is continued for two weeks *If there is not then a definite increase in the hemoglobin the dose should be doubled* If this dose does not cause a satisfactory response then (1) excessive hemorrhage may be causing the patient to lose blood faster than it can be formed (2) some infection renal disease (with increase in the nonprotein nitrogen of the blood)

hypothyroidism or vitamin C or protein deficiency may be complicating the case or (3) the patient may not be taking the preparation as advised

Other satisfactory iron preparations are ferrous gluconate (0 65 gram [10 grains] three times daily after meals) and ferrous carbonate (0 32 gram [5 grains] three pills taken three times daily with each meal) For children, the elixir of ferrous sulphate may be given in doses of 4 cc (0 12 gram 2 grains) three times daily after meals

Blood transfusions in these patients are useful for two reasons—because red blood cells and hemoglobin are actually given and because each 500 cc of blood contains 250 milligrams of iron The response to iron medication is so satisfactory, however that they are rarely indicated

Fatal poisoning from ferrous sulphate has been reported in infants after a gross overdose of tablets containing ferrous sulphate copper, and manganese (26 tablets) The subject is reviewed by Pram (1949) who suggests that destruction of the gastric mucosa by the excessive ferrous sulphate leads to lethal hepatic damage Parents should be warned to prevent children from taking a great many coated tablets of iron The possibility that harm may result from excessive amounts of iron given either intravenously as an iron preparation or as part of the hemoglobin molecule with blood transfusions must also be taken into consideration Such a complication as hemachromatosis is not likely to occur however till a dose of 25 grams has been given

In my experience it is usually not necessary to give other medication than iron Many patients with this type of anemia have an achlorhydria but the administration of dilute hydrochloric acid does not seem to enhance the utilization of iron importantly nor does it seem to be necessary to alleviate the gastric symptoms Although iron is not utilized efficiently except in the presence of small amounts of copper, there is enough copper in the patient s diet for this purpose and in addition, most iron preparations contain copper Vitamin supplements are not usually necessary unless there are special indications for their use, and special diets are not needed, except for patients with grossly abnormal dietary habits

With effective iron therapy there is usually a moderate rise in the reticulocytes of the peripheral blood within the first ten days, but it is less than that observed after effective therapy in patients with pernicious anemia Usually, at the beginning of the week there is a rise in hemoglobin This rise continues at the rate of about 1 per cent (0 15 to 0 2 gram) daily until the blood is normal

*Parenteral Iron* —Occasionally, when the patient is unable to tolerate iron orally, it is advantageous to give it parenterally Until recently iron could not be given by this route without risk of severe reaction There is now available a stable preparation saccharated oxide of iron, which appears to be satisfactory for intravenous use It has received extensive clinical trials especially in England and been found to be a safe and efficient preparation, easily administered without reaction *when given slowly* One preparation Ferrivenin' (Benger) used in England is prepared in 5 cc ampules containing 100 milligrams of elemental iron in a 2 per cent solution It is suggested that the contents of one ampule (100 milligrams of iron) will raise the hemoglobin 4 per cent hence the total amount required for a given patient may be approximated On the first day a dose of 1 5 cc may be given on the second day a dose of 3 cc on subsequent days doses of 5 cc until the blood is normal

*Prognosis* —This varies with the variety of hypochromic anemia In the nutritional anemia of children in chlorosis and idiopathic hypochromic anemia the effect of iron is prompt and all that is to be desired but there is an ever present tendency to a recurrence The latter condition frequently disappears after the menopause Iron medication should be continued for long periods of time and the patients observed until the periods of rapid growth or in the case of adolescent and adult women until there are no longer excessive demands for iron as those associated with menstruation pregnancy and lactation In the variety of anemia due to chronic hemorrhage the outlook is dependent upon the underlying cause of the bleeding The anemia is always amenable to iron

therapy if the loss of blood can be controlled and in the absence of an infection Even in cases of blood loss due to malignancy as with carcinoma of the stomach the anemia may often be corrected in part at least and the patient thereby greatly benefited temporarily

## PERNICIOUS ANEMIA

By CYRUS C STURGIS M D

*Synonyms* —Addisonian anemia Addison Biermer anemia Primary anemia

*Definition* —Pernicious anemia a chronic disease affecting both sexes equally but most commonly occurring in the white race in temperate climates at middle life or later is a macrocytic normochromic anemia with a megaloblastic bone marrow a persistent histamine resistant achlorhydria and frequently a recurrent glossitis and degenerative changes in the peripheral nerves and spinal cord The anemia is thought to be due to a failure of the gastric glands to secrete Castle s enzyme like intrinsic factor this failure results in lack of normal maturation of the red blood cells in the bone marrow There is a prompt response to specific therapy but untreated cases progress slowly usually with remissions to death

*Etiology* —Pernicious anemia is a relatively common disease in North America for of every 1000 patients admitted to a general hospital there are 3 or 4 with the disease The incidence has been given as 6 9 per 100 000 in the United States 9 1 in Canada, and 9 18 in Sweden (Askanazy 1937) The apparent increase in the prevalence of the condition is due undoubtedly to more accurate methods of diagnosis and to the fact that as the result of increased longevity a greater number of persons now live to the age when the disease commonly occurs

This variety of anemia unquestionably has a greater incidence in certain races than in others It is observed frequently in the United States Canada England Scotland Ireland and the countries of Northern Europe whereas it is rarely seen in natives of the tropics China or South America It probably never occurs in pure blooded Negroes but has been observed in mulattoes It is distinctly a disease of the white race in temperate climates

Symptoms develop most frequently between forty and sixty five years of age If a group of patients with pernicious anemia are considered according to their age and the number of individuals living at the various ages however the highest incidence is between sixty five and seventy years True pernicious anemia probably never develops in young children but the onset may occasionally be during the second decade of life It is not rare in individuals between twenty and thirty years of age Cases have been reported in infants and young children but they probably have had the megaloblastic anemia of infancy a disease which differs from pernicious anemia in several important aspects

The two sexes are affected with equal frequency

The hereditary occurrence of pernicious anemia is now an established fact A familial incidence of between 10 and 20 per cent is the one usually given but it is probably higher It has been reported in identical twins and as many as five cases have been observed in siblings Not only are outspoken cases of pernicious anemia observed in the same family but a number of the other immediate relatives may have achylia gastrica recurrent glossitis or minor changes

hypothyroidism or vitamin C or protein deficiency may be complicating the case or (3) the patient may not be taking the preparation as advised

Other satisfactory iron preparations are ferrous gluconate (0.65 gram [10 grains] three times daily after meals) and ferrous carbonate (0.32 gram [5 grains] three pills taken three times daily with each meal) For children, the elixir of ferrous sulphate may be given in doses of 4 cc (0.12 gram 2 grains) three times daily after meals

Blood transfusions in these patients are useful for two reasons—because red blood cells and hemoglobin are actually given and because each 500 cc of blood contains 250 milligrams of iron The response to iron medication is so satisfactory however that they are rarely indicated

Fatal poisoning from ferrous sulphate has been reported in infants after a gross overdose of tablets containing ferrous sulphate copper, and manganese (26 tablets) The subject is reviewed by Prain (1949) who suggests that destruction of the gastric mucosa by the excessive ferrous sulphate leads to lethal hepatic damage Parents should be warned to prevent children from taking a great many coated tablets of iron The possibility that harm may result from excessive amounts of iron given either intravenously as an iron preparation or as part of the hemoglobin molecule with blood transfusions must also be taken into consideration Such a complication as hemachromatosis is not likely to occur however till a dose of 25 grams has been given

In my experience, it is usually not necessary to give other medication than iron Many patients with this type of anemia have an achlorhydria, but the administration of dilute hydrochloric acid does not seem to enhance the utilization of iron importantly nor does it seem to be necessary to alleviate the gastric symptoms Although iron is not utilized efficiently except in the presence of small amounts of copper, there is enough copper in the patient s diet for this purpose and, in addition, most iron preparations contain copper Vitamin supplements are not usually necessary, unless there are special indications for their use and special diets are not needed, except for patients with grossly abnormal dietary habits

With effective iron therapy, there is usually a moderate rise in the reticulocytes of the peripheral blood within the first ten days but it is less than that observed after effective therapy in patients with pernicious anemia Usually, at the beginning of the week there is a rise in hemoglobin This rise continues at the rate of about 1 per cent (0.15 to 0.2 gram) daily until the blood is normal

*Parenteral Iron* —Occasionally when the patient is unable to tolerate iron orally, it is advantageous to give it parenterally Until recently iron could not be given by this route without risk of severe reaction There is now available a stable preparation saccharated oxide of iron which appears to be satisfactory for intravenous use It has received extensive clinical trials especially in England and been found to be a safe and efficient preparation easily administered without reaction *when given slowly* One preparation Ferrivenin (Benger) used in England is prepared in 5 cc ampules containing 100 milligrams of elemental iron in a 2 per cent solution It is suggested that the contents of one ampule (100 milligrams of iron) will raise the hemoglobin 4 per cent hence the total amount required for a given patient may be approximated On the first day a dose of 1.5 cc may be given on the second day a dose of 3 cc on subsequent days doses of 5 cc until the blood is normal

*Prognosis* —This varies with the variety of hypochromic anemia In the nutritional anemia of children in chlorosis and idiopathic hypochromic anemia the effect of iron is prompt and all that is to be desired but there is an ever present tendency to a recurrence The latter condition frequently disappears after the menopause Iron medication should be continued for long period of time and the patients observed until the periods of rapid growth or in the case of adolescent and adult women until there are no longer excessive demands for iron as those associated with menstruation pregnancy and lactation In the variety of anemia due to chronic hemorrhage the outlook is dependent upon the underlying cause of the bleeding The anemia is always amenable to iron

glands in the mucosa of the cardiac end of the stomach the area of principal atrophy in patients with pernicious anemia secrete the intrinsic factor as well as hydrochloric acid and pepsin In various species however the site may be different The cause of the functional failure of the gastric glands is obscure

The cause of the changes in the nervous system is not known, but the knowledge that is available concerning their etiology plus the recent information which has been acquired in regard to the vitamins suggests that a deficiency of a vitamin or a vitamin like material perhaps related to the B complex, a more pronounced deprivation might produce changes in the lateral columns It is certainly true that the neurologic manifestations invariably advance in a set order which suggests first peripheral nerve involvement, next changes in the posterior column, and finally lateral column lesions

*Pathology* —No single pathologic change is recognized as characteristic of pernicious anemia The most constant anatomic findings are the anemia widespread fatty degeneration of many parenchymatous viscera and the muscles hyperplastic changes in the bone marrow with the megaloblasts as the predominating cells degenerative

Fig 181 —Cross section of the spinal cord (Sturgis Diseases of the Blood courtesy of Charles C Thomas )

may play the leading role in the causation of these lesions The persistent achlorhydria in patients with pernicious anemia may be an important factor in the production of this, as absorption may be impaired and thereby cause a vitamin insufficiency despite an adequate dietary intake It is plausible that a total or partial lack of some substance acting with varying degrees of intensity over a long period might produce different neurologic changes thus the earliest evidence of a shortage could be changes in the peripheral nerves associated with paresthesia of the extremities a further intensification of the deficiency might then cause lesions of the posterior column and finally changes in the peripheral nerves, and similar lesions involving the posterior and lateral columns of the spinal cord The process is thought to attack first the myelin sheaths at which time it is probably a reversible condition the later destruction of the axis cylinders is probably a permanent change Unless anti pernicious anemia therapy has been given there is an absence of glial activity

Gastroscopic and observations at necropsy indicate that atrophic gastritis is present in patients with pernicious anemia and combined degeneration of the cord The involvement is chiefly in the region of the fundus In this area the specific glandular

in the blood, suggesting an early or incomplete type of pernicious anemia. It is generally accepted that achlorhydria, and probably a diminution of the intrinsic factor, are often *hereditary precursors of pernicious anemia*. There is no evidence to indicate that the disorder is sex linked or sufficient data to permit a conclusion as to whether the trait for the disease is dominant or recessive.

Any statement now made concerning the etiology of pernicious anemia must be considered purely tentative. New information is being accumulated so rapidly that overnight our views may be revised radically. With the available information, however, *the theory advanced by Castle in 1929* appears plausible provided certain modifications are accepted. This observer has demonstrated that an unidentified substance in the diet (the extrinsic factor) when taken into the stomach reacts with an enzyme-like material in the gastric secretions (the intrinsic factor) to produce a product essential to the development of the red blood cells in the bone marrow. In pernicious anemia, the intrinsic factor is diminished, *hence maturation of the red blood cells in* the bone marrow does not proceed normally.

Observations in recent years have amplified this theory, but nothing has been discovered to date which is incompatible with the fundamental principles elaborated by Castle. It is now recognized that the normal diet contains at least two materials necessary to the development of the red blood cells—pteroylglutamic acid (folic acid) and vitamin $B_{12}$. There is strongly suggestive evidence, however, to indicate that neither is in food in readily utilizable form: folic acid is in the conjugated or inactive form, and vitamin $B_{12}$ must *also be activated or altered in some manner*.

It has been suggested by Hall, Bethell and their associates *that the change produced* in vitamin $B_{12}$ is accomplished by the intrinsic factor, which (1) makes it absorbable by changing its physical or chemical characteristics, (2) prevents its destruction by gastrointestinal secretions or (3) averts the deleterious effects which may be produced by intestinal bacteria. The role played by "apoerythein," the heat labile substance in normal gastric juice, is uncertain. Ternberg and Eakin, who discovered it in 1949, *demonstrated that this* material combines with vitamin $B_{12}$ to make the latter unavailable for the growth of certain bacteria.

Once $B_{12}$ and conjugated folic acid are absorbed by the body, the events leading to their actions in the development of the red blood cells in the bone marrow are not known. The vitamin may convert the inactive conjugated form of folic acid into its free and active type, but there are certain *objections to this theory. If this did occur, it* could be assumed that the liberated folic acid supplied the necessary stimulus to the development of the red blood cells in the bone marrow and that, under the influence of the required amount of this material, they matured at a physiologic rate which maintained the red blood cell count of the circulating blood at a normal level.

If such a theory were accepted, it must be acknowledged that the primary cause *of pernicious anemia is a reduced rate* of production of red blood cells in the bone marrow and that the increased destruction of erythrocytes in the disease was of secondary importance. This concept assumes that pernicious anemia is due to the body's inability to absorb or utilize vitamin $B_{12}$ normally, which results from a deficiency of intrinsic factor in the gastric juice. The result would be failure to convert the diet's conjugated folic acid into free and active folic acid. Assuming the latter is essential to the normal rate of development of the red blood cells, reduced production of red blood cells in the bone marrow would follow, together with the development of an anemia due to diminished erythrocyte formation.

*No available information* indicates the ultimate cause of the intrinsic factor deficiency. It seems logical to attribute it, however, to some inherited defect of the stomach. Clinical observations have shown that a chronic gastritis commonly occurs during the disease but disappears during remissions. Furthermore, careful studies in *man have demonstrated* an atrophy of the upper two thirds of the gastric mucosa which ends sharply at the junction with the pyloric region. It appears probable *that the*

glands in the mucosa of the cardiac end of the stomach the area of principal atrophy in patients with pernicious anemia, secrete the intrinsic factor as well as hydrochloric acid and pepsin In various species however the site may be different The cause of the functional failure of the gastric glands is obscure

The cause of the changes in the nervous system is not known but the knowledge that is available concerning their etiology plus the recent information which has been acquired in regard to the vitamins suggests that a deficiency of a vitamin or a vitamin like material perhaps related to the B complex may play the leading role in the causation of these lesions The persistent achlorhydria in patients with pernicious anemia may be an important factor in the production of this as absorption may be impaired and therby cause a vitamin insufficiency despite an adequate dietary intake It is plausible that a total or partial lack of some substance acting with varying degrees of intensity over a long period might produce different neurologic changes thus the earliest evidence of a shortage could be changes in the peripheral nerves associated with paresthesia of the extremities a further intensification of the deficiency might then cause lesions of the posterior column and finally a more pronounced deprivation might produce changes in the lateral columns It is certainly true that the neurologic manifestations invariably advance in a set order which suggests first peripheral nerve involvement next changes in the posterior column and finally lateral column lesions

*Pathology* —No single pathologic change is recognized as characteristic of pernicious anemia The most constant anatomic findings are the anemia widespread fatty degeneration of many parenchymatous viscera and the muscles hyperplastic changes in the bone marrow with the megaloblasts as the predominating cells degenerative changes in the peripheral nerves and similar lesions involving the posterior and lateral columns of the spinal cord The process is thought to attack first the myelin sheaths at which time it is probably a reversible condition the later destruction of the axis cylinders is probably a permanent change Unless anti pernicious anemia therapy has been given there is an absence of glial activity

*Fig 181* —Cross section of the spinal cord (Sturgis Diseases of the Blood courtesy of Charles C Thomas )

Gastroscopic and observations at necropsy indicate that atrophic gastritis is present in patients with pernicious anemia and combined degeneration of the cord The involvement is chiefly in the region of the fundus In this area the specific glandular

elements, the chief and parietal cells disappear and the changes of interstitial gastritis are present The normal glandular structure is maintained in the pylorus and the duodenum There is therefore a histologic basis for the absence of hydrochloric acid and pepsin in the gastric secretions and also for the lack of intrinsic factor, if it is accepted that they arise from glands in the area of the fundus The gastric changes are probably not the end result of an inflammatory process but their cause is obscure

It was recognized many years ago by Hunter that the liver kidneys and spleen may contain deposits of hemosiderin, an iron-containing pigment which is derived from hemoglobin

Peabody, by means of biopsies, observed that during relapse the essential histologic lesions in the bone marrow is a proliferation of megaloblasts which results in a hyperplastic but functionally inefficient marrow as these cells fail to differentiate toward mature erythrocytes This state has been designated as a maturation arrest During a remission there is a great relative increase of normoblasts and mature red blood cells in the marrow whereas the megaloblasts are rare Sternal puncture in a patient with pernicious anemia in relapse shows a pre

Fig 183 —Nucleated red cells E Erythroblasts (1 2 and 3) The cells are large the cytoplasm is basophilic and the chromatin of the nucleus is disposed in strands These cells are younger than normoblasts N Normoblasts The cells are smaller and the cytoplasm is less basophilic than the erythroblast The chromatin of the nucleus is dense or pyknotic In 4 and 5 the nucleus is being extruded In 1 2 and 6 the nucleus is breaking up as indicated by the fleur de-lis shape (Haden s Principles of Hematology )

dominance of megaloblasts and their progenitors Following treatment there is a prompt change, even after a single day by which time most of the cells are in a middle or advanced stage of maturation There is also a rapid transition to normal in the neutrophils following therapy

*Symptoms* — These may be divided into four groups depending on whether they are referable to the anemia the gastro intestinal tract the nervous system or the cardio vascular system In a very large percentage of patients there are usually manifestations of varying degree representing each group According to Minot the earliest complaints are referable to the anemia in 33 per cent of the patients to the digestive tract in 31 per cent to the nervous system in 26 per cent, and the heart in 10 per cent The important symptoms which are due to the anemia are weakness ease of fatigue pallor and dizziness Those associated with the gastro intestinal system are anorexia recurrent attacks of glossitis, nausea, vomiting mild epigastric discomfort and either constipation or diarrhea, or an alternation of the two It should be emphasized that about 12 per cent of patients with pernicious anemia have associated gall bladder disease which should always be suspected in the presence of persistent abdominal complaints especially if they continue after adequate anti pernicious anemia therapy has been given The most common evidence of in

regardless of the amounts of specific therapy given The hemoglobin during a relapse shows a drop which is less than the red blood-cell count, and as a result the color index is 1 or greater A high color index is constantly observed in uncomplicated pernicious anemia

The most characteristic finding in a stained blood film is the presence of large, round or oval red blood cells which are well filled with hemoglobin These macrocytes as they are called may make up 25 to 30 per cent of all the red blood cells and parallel in number roughly the severity of the anemia In addition there are present a variable number of small red blood cells microcytes which may measure only 3 or 4 microns in diameter Poikilocytosis or irregularity in shape of the red blood cells is almost always observed when the anemia is severe There is an increase in the mean corpuscular volume to between 100 and 130 cubic microns, the mean corpuscular hemoglobin concentration to between 32 and 35 per cent and the mean corpuscular hemoglobin from 30 to 52 micromicrograms Measurement of the diameters of the erythrocytes by the Price-Jones procedure shows a characteristic curve when an anemia is present The greatest percentage of red blood cells measure between 9 and 9 5 microns but there is an extreme variation in the size which may range from 3 5 to 14 microns While the measurement curve which is seen in pernicious anemia may also be present in other macrocytic anemias it is wholly different from that observed in the blood of patients with normocytic or iron-deficiency anemias

Various forms of immature red blood cells may be present such as normoblasts megaloblasts cells showing diffuse basophilia or stippling and less frequently Howell Jolly bodies and Cabot s ring forms With a special vital stain such as cresyl blue reticulocytes may be demonstrated but in relapse they are rarely present in numbers greater than 1 per cent of the red cells It should be emphasized that immature red blood cells in the peripheral blood are not essential to the diagnosis of pernicious anemia They appear only when the patient is improving and the red blood-cell count is rising

There is practically always a reduction in the number of platelets A reduced white-blood cell count is characteristic of pernicious anemia during a relapse It is exceedingly rare to observe a leukocytosis even with an active infection when the red blood-cell count is low With antipernicious anemia treatment, however the leukocyte count may be excessively high in the presence of an infection

*Other Laboratory Tests —Gastric Analysis* —One of the most important laboratory procedures from the standpoint of diagnosis is an examination of the gastric contents for free hydrochloric acid In our series of almost two thousand patients at the Simpson Memorial Institute in whom a fractional gastric analysis was done there was a complete absence of hydrochloric acid in every single case and a uniformly low total acidity Three to five specimens were removed in each instance and in practically all of the patients the analysis followed the injection of 0 5 to 1 mg of histamine intramuscularly Not only does the achlorhydria exist at the time the clinical manifestations of pernicious anemia are apparent but it is now well established that it may be present many years prior to their appearance and probably exists from birth It is known also that the absence of free hydrochloric acid persists when the blood returns to normal and also when the patient is symptomless either as a result of a spontaneous or therapeutically induced remission The facts regarding the achlorhydria of pernicious anemia are so well established that the presence of free hydrochloric acid in the gastric contents of a patient who is suspected of having pernicious anemia practically eliminates this diagnosis regardless of other convincing evidence of the disease In addition to the lack of free hydrochloric acid pepsinogen (the precursor of pepsin) is rarely if ever present in the gastric contents

*Hyperbilirubinemia* —It is well established that the bilirubin content of the blood serum is always increased when the red blood-cell count is low and that it falls to normal as the red cell count rises While it may not be accepted that the amount of bilirubin in the

volvement of the nervous system is numbness of the hands and feet, weakness and spasticity of the muscles of the lower extremities, ataxia which is due to the loss of the sense of motion and position of the lower extremities and loss of control of the sphincter of the bladder Cardiovascular manifestations due mainly to the anemia are dyspnea on exertion palpitation sometimes edema of the ankles, and occasionally, the cardiac pain characteristic of angina pectoris

*The history of the average case is one of* gradually developing weakness in a person of middle age which becomes progressively worse until it is often completely incapacitating Coincident with the development of this symptom, pallor, sometimes with a yellowish tint, dyspnea and palpitation on exertion and occasionally edema of the ankles are observed About 90 per cent of the patients complain of numbness and tingling of the hands and feet It is important to note that this almost always involves all four extremities, and it is persistent, although it may vary in intensity Recurring attacks of sore tongue occur in more than one-half of the patients and in rare instances it is the initial and outstanding symptom This complaint may be only a mild burning discomfort or an extensive involvement which may interfere seriously with the ingestion of food As the anemia becomes pronounced, nausea vomiting fever and delirium may appear

*Physical Examination* —Usually reveals a fairly well nourished individual, although there is commonly a loss of 10 to 20 pounds in body weight during the illness A pronounced pallor which may have an associated yellowish tint may be present thereby giving rise to the so called lemon yellow or grape fruit appearance to the skin and conjunctiva this is observed much less commonly now than in the past The hair is usually partly or completely gray and the eyes are most frequently colored the lighter shades of green or blue Not infrequently the tongue over the dorsum, has a smooth appearance due to atrophy of the papillae In some instances it may be a fiery red as a result of the associated glossitis Rarely is the tongue coated during the period of severe anemia in fact, a heavily coated tongue casts some doubt on the diagnosis of pernicious anemia The lungs are usually normal and the heart shows no conspicuous changes except that frequently a soft systolic (*hemic*) *murmur* is present, and there may be borderline enlargement of the left ventricle The spleen and liver are rarely palpable The presence *of splenomegaly at once suggests some other* disease than pernicious anemia Not infrequently the abdomen is distended which may be a troublesome symptom especially in patients with spinal cord involvement A slight to moderate edema of the ankles may be present when the red blood cell count is below 2 000 000 per c mm When the anemia becomes severe a hemorrhagic tendency associated with a diminution in platelets may develop as evidenced by petechiæ and ecchymoses retinal hemorrhages epistaxis and bleeding from other sources Objective evidence of degenerative changes in the posterior and lateral columns of the spinal cord is commonly encountered Those due to posterior column involvement are loss of vibratory sense and the sense of motion and position of the lower extremities ataxia and a positive Romberg sign Changes in the lateral columns are responsible for evidences of spastic paraplegia exaggerated knee jerks and a bilateral positive Babinski sign Not infrequently cerebral manifestations such as mild depression irritability impaired memory occasionally delusions and hallucinations and even maniacal outbursts may be present

Fever is commonly present when the red blood cell count falls to a low level This disappears when the anemia becomes less In some instances it may be due to a cystitis which is associated with a loss of control of the sphincters of the bladder and an infected residual urine

*The Blood* —The red blood cell count in pernicious anemia during a relapse is usually below 2 000 000 per c mm and it may fall to 500 000 red cells per c mm or less In a spontaneous remission the count may reach normal but it is usually between 3 000 000 and 4 000 000 cells per c mm In therapeutically induced remissions it is almost always above 4 000 000 per c mm and in *some instances it may reach* 6 000 000 never does it reach abnormally high levels

regardless of the amounts of specific therapy given. The hemoglobin during a relapse shows a drop which is less than the red-blood-cell count, and as a result the color index is 1 or greater. A high color index is *constantly observed in uncomplicated pernicious anemia*.

The most characteristic finding in a stained blood film is the presence of large, round or oval red blood cells which are well filled with *hemoglobin*. These *macrocytes, as they are called*, may make up 25 to 30 per cent of all the red blood cells and parallel in number roughly the severity of the anemia. In addition, there are present a variable number of small red blood cells, *microcytes*, which may measure only 3 or 4 microns in diameter. Poikilocytosis, or irregularity in shape of the red blood cells, is almost always observed when the anemia is severe. There is an increase in the mean corpuscular volume to between 100 and 130 cubic microns, the mean corpuscular hemoglobin concentration to between 32 and 35 per cent, and the mean corpuscular hemoglobin from 30 to 52 *micromicrograms*. Measurement of the diameters of the erythrocytes by the Price-Jones procedure shows a characteristic curve when an anemia is present. The greatest percentage of red blood cells measure between 9 and 9.5 microns, but there is an extreme variation in the size which may range from 3.5 to 14 microns. While the measurement curve which is seen in pernicious anemia may also be present in *other macrocytic anemias, it is wholly different* from that observed in the blood of patients with normocytic or iron-deficiency anemias.

Various forms of immature red blood cells may be present, such as normoblasts, megaloblasts, cells showing diffuse basophilia or stippling, and less frequently *Howell-Jolly bodies and Cabot's ring forms*. With a special vital stain, such as cresyl blue, reticulocytes may be demonstrated, but in relapse they are *rarely present in* numbers greater than 1 per cent of the red cells. It should be emphasized that immature red blood cells in the peripheral blood are not essential to the diagnosis of pernicious anemia. They appear only when the *patient is improving* and the red blood-cell count is rising.

There is practically always a reduction in the number of platelets. A reduced white-blood-cell count is characteristic of pernicious anemia during a relapse. It is exceedingly rare to observe a leukocytosis even with an active infection when the red blood-cell count is low. With antipernicious anemia treatment, however, the leukocyte count may be excessively high *in the presence* of an infection.

*Other Laboratory Tests.—Gastric Analysis.*—One of the most important laboratory procedures from the standpoint of diagnosis is an examination *of the gastric contents for* free hydrochloric acid. In our series of almost two thousand patients at the Simpson Memorial Institute in whom a fractional gastric analysis was done, there was a complete absence of hydrochloric acid in every single case and a uniformly low total acidity. Three to five specimens were removed in each instance, and in practically all of the patients the analysis followed the injection of 0.5 to 1 mg. of histamine intramuscularly. Not only does the achlorhydria exist at the time the clinical manifestations of pernicious anemia are apparent, but it is now well established that it may be present many years prior to their appearance and probably exists from birth. It is known also that the absence of free hydrochloric acid persists when the blood returns to normal and also when the patient is symptomless either as a result of a spontaneous or therapeutically induced remission. The facts regarding the achlorhydria of pernicious anemia are so well established that the presence of free hydrochloric acid in the gastric contents of a patient who is suspected of having pernicious anemia practically eliminates this diagnosis regardless of other convincing evidence of the disease. In addition to the lack of free hydrochloric acid, pepsinogen (the precursor of pepsin) is rarely, if ever, present in the gastric contents.

*Hyperbilirubinemia.*—It is well established that the bilirubin content of the blood serum is always increased when the red blood-cell count is low, and that it falls to normal as the red cell count rises. While it may not be accepted that the amount of bilirubin in the

volvement of the nervous system is numbness of the hands and feet, weakness and spasticity of the muscles of the lower extremities, ataxia which is due to the loss of the sense of motion and position of the lower extremities and loss of control of the sphincter of the bladder Cardiovascular manifestations due mainly to the anemia are dyspnea on exertion, palpitation sometimes edema of the ankles, and occasionally, the cardiac pain characteristic of angina pectoris

The history of the average case is one of gradually developing weakness in a person of middle age which becomes progressively worse until it is often completely incapacitating Coincident with the development of this symptom pallor, sometimes with a yellowish tint dyspnea and palpitation on exertion and occasionally edema of the ankles are observed About 90 per cent of the patients complain of numbness and tingling of the hands and feet It is important to note that this almost always involves all four extremities and it is persistent although it may vary in intensity Recurring attacks of sore tongue occur in more than one half of the patients, and in rare instances it is the initial and outstanding symptom This complaint may be only a mild burning discomfort or an extensive involvement which may interfere seriously with the ingestion of food As the anemia becomes pronounced, nausea vomiting fever and delirium may appear

*Physical Examination* —Usually reveals a fairly well nourished individual although there is commonly a loss of 10 to 20 pounds in body weight during the illness A pronounced pallor which may have an associated yellowish tint may be present thereby giving rise to the so-called lemon yellow or grapefruit appearance to the skin and conjunctiva this is observed much less commonly now than in the past The hair is usually partly or completely gray and the eyes are most frequently colored the lighter shades of green or blue Not infrequently the tongue over the dorsum has a smooth appearance due to atrophy of the papillae In some instances it may be a fiery red as a result of the associated glossitis Rarely is the tongue coated during the period of severe anemia in fact a heavily coated tongue casts some doubt on the diagnosis of pernicious anemia The lungs are usually normal and the heart shows no conspicuous changes except that frequently a soft systolic (hemic) murmur is present, and there may be borderline enlargement of the left ventricle The spleen and liver are rarely palpable The presence of splenomegaly at once suggests some other disease than pernicious anemia Not infrequently the abdomen is distended, which may be a troublesome symptom especially in patients with spinal cord involvement A slight to moderate edema of the ankles may *be present when the red blood cell count is* below 2 000 000 per c mm When the anemia becomes severe a hemorrhagic tendency associated with a diminution in platelets may develop as evidenced by petechiae and ecchymoses, retinal hemorrhages epistaxis and bleeding from other sources Objective evidence of degenerative changes in the posterior and lateral columns of the spinal cord is commonly encountered Those due to posterior column involvement are loss of vibratory sense and the sense of motion and position of the lower extremities ataxia, and a positive Romberg sign Changes in the lateral columns are responsible for evidences of spastic paraplegia exaggerated knee jerks, and a bilateral positive Babinski sign Not infrequently cerebral manifestations such as mild depression irritability, impaired memory, occasionally delusions and hallucinations and even maniacal outbursts may be present

Fever is commonly present when the red blood cell count falls to a low level This disappears when the anemia becomes less In some instances it may be due to a cystitis which is associated with a loss of control of the sphincters of the bladder and an infected residual urine

*The Blood* —The red blood-cell count in pernicious anemia during a relapse is usually below 2 000 000 per c mm and it may fall to 500 000 red cells per c mm or less In a spontaneous remission the count may reach normal but it is usually between 3 000 000 and 4 000 000 cells per c mm In therapeutically induced remissions it is almost always above 4 000 000 per c mm and in some instances it may reach 6 000 000 never does it reach abnormally high levels

responds to treatment with crude liver extracts autolyzed yeast extracts and folic acid Relapses do not occur if the diet is corrected

*Refractory megaloblastic anemia* as described by Davidson (1948) is a macrocytic anemia with megaloblastic hyperplasia of the bone marrow It occurs in both sexes and in persons between 12 and 70 plus The symptoms and signs are usually only those of a severe anemia Acute glossitis is rare but the chronic form of the complaint is common There are no objective signs of involvement of the central nervous system In slightly over half the *patients there is a histamine-resistant achlorhydria* and in these the differential diagnosis from pernicious anemia is impossible until it is demonstrated that there is failure to respond to parenteral injections of liver extract According to Davidson (1948) these cases would conform to the condition designated as *Achrestic anemia* by Israels and Wilkinson (1936) Proteolyzed liver or folic acid apparently has been employed successfully for this condition at least it is worth a thorough trial It is suggested that possibly this anemia is associated with a dietary deficiency (of conjugated folic acid) malabsorption of some essential dietary constituent or some disturbance in liver function (Davidson)

A macrocytic anemia may occur in patients who have had *total gastrectomy intestinal anastomoses or strictures* This is due either to removal of the intrinsic factor to malabsorption or to stagnation of the intestinal contents probably with some alteration in the intestinal flora Glossitis and neurological changes may be present Response is obtained to liver extract or vitamin $B_1$ given parenterally or to folic acid given parenterally or orally In patients with intestinal disturbances the intrinsic factor is present in the stomach

A small percent possibly a third of the cases with *cirrhosis of the liver* have a macrocytic anemia The rest have a normocytic or microcytic anemia probably dependent on the amount of hemorrhage There is a leukopenia or a normal white blood-cell count The platelet count is low normal or distinctly diminished There is usually a macronormoblastic erythropoiesis in the bone marrow A megaloblastic marrow may occur but it is rare The pathogenesis of the anemia in cirrhosis of the liver independent of bleeding is obscure Failure of adequate storage of the erythrocyte-maturing factor has been suggested as a cause of the macrocytic anemia but this view is not entirely acceptable for this factor has been demonstrated in the livers of patients succumbing to the disease The possibility that the anemia may be on a nutritional basis must be considered since patients with cirrhosis almost always eat a deficient diet, usually one low in protein Liver extract given parenterally and folic acid *given orally or parenterally* may be used therapeutically but they do not always produce satisfactory results The differential diagnosis of pernicious anemia from cirrhosis should not be difficult in cirrhosis neurological involvement is absent ascites may be present cutaneous angiomas are indicative of extensive hepatic involvement and liver function tests are positive

A macrocytic anemia with megaloblastic hyperplasia of the bone marrow may be due to infestation with the *broad tapeworm diphyllobothrium latum* (which occurs most frequently in Finland but patients may occasionally acquire the infestation in North America) The anemia and the bone marrow changes are identical with those observed in true Addisonian pernicious anemia A histamine resistant achlorhydria is usually present but free acid may be detected in persons under twenty years of age Neurological changes are not observed The associated anemia occurs in far below one per cent of the cases of the infestation Apparently the cause of the anemia is an interference in some obscure way with the interaction between the extrinsic and intrinsic factors Prompt control of the anemia can be accomplished by the injection of liver extract or folic acid even when the parasite remains in the intestinal tract The simplest method of treatment however is removal of the worm It should be kept in mind that in a country such as Finland where both the infestation and pernicious anemia are common patients may be encountered with true pernicious anemia in whom the parasite is also present

serum is an index of the degree of blood destruction nevertheless it is a fairly good index of the course of the disease and as an aid to diagnosis There are two clinical methods for estimating the bilirubin in the blood serum These are the van den Bergh reaction and the icterus index The upper limit of normal for the former test is 0 7 mg of bilirubin per 100 cc of serum, whereas the normal limits of the icterus index are expressed in the arbitrary figures 4 to 6 In pernicious anemia during relapse the icterus index averages between 20 and 25 and the indirect van den Bergh reaction gives *a reading averaging from about* 1 0 *to* 1 5 mg per 100 cc of blood although occasionally higher figures are noted

*Diagnosis* —Ordinarily the diagnosis of pernicious anemia is not difficult If an adult complains of the usual symptoms of an anemia such as weakness pallor dyspnea and palpitation, and there is a yellowish tint *to the skin and conjunctiva the most* likely diagnosis is pernicious anemia If additional complaints include persistent numbness of the hands and feet and recurrent attacks of glossitis and a histamine resistant achlorhydria is present the diagnosis is almost certain even before the blood is examined Other findings which are helpful *are the characteristic blood picture* hyperbilirubinemia a history of remissions and findings suggesting subacute combined degeneration of the spinal cord It is of assistance to keep in mind that there are seven cardinal points of fundamental diagnostic importance in relation to pernicious anemia and if all or even a majority are present the diagnosis is at once suggested or established These are (1) achlorhydria (2) macrocytosis (3) a high color index and normal mean corpuscular *hemoglobin* concentration (4) paresthesia of all four extremities, (5) recurrent glossitis (6) leukopenia and (7) a favorable response to antipernicious anemia therapy

## Macrocytic Anemia Other than Pernicious Anemia

*Differential Diagnosis* —A number of conditions, in addition to pernicious anemia are characterized by a macrocytic anemia with megaloblastic hyperplasia of the bone marrow It is impossible to differentiate them from pernicious anemia by examination of the blood and bone marrow alone These are the macrocytic anemias associated with (1) sprue, (2) pregnancy and the *puerperium* (3) *deficient nutritional states* (4) refractory megaloblastic anemia (Achrestic anemia) (5) total gastrectomy intestinal anastomosis, and stenosis (6) cirrhosis of the liver, (7) megaloblastic anemia of infancy, and (8) fish tapeworm infestation

*Sprue* and the closely allied conditions, idiopathic steatorrhea and coeliac disease in infancy are often associated with a macrocytic anemia and a megaloblastic bone marrow In these conditions especially in sprue the stools are voluminous foamy greasy, liquid gray in color and foul in odor About half the patients have an achlorhydria There are no neurological changes There may be a recurrent glossitis Liver extract and $B_{12}$ given parenterally are highly effective in the treatment of this disease as is folic acid administered orally or parenterally with a diet high in protein There is a tendency to relapse when the treatment is discontinued

*Macrocytic anemia of pregnancy* occurs usually in women under forty years of age Free *hydrochloric acid is present in the* gastric secretions in about half the cases Glossitis and neurological manifestations are absent Recovery follows treatment with folic acid or disappears after the termination of pregnancy The most efficient form of therapy is with folic acid although some improvement may follow the use of liver extract The disease apparently is refractory to treatment with $B_{12}$ (Bethell)

*Nutritional macrocytic anemia* may occur *in any patient on a persistently abnormal* diet especially one deficient in protein This condition has been observed most commonly in the tropics It may occur at any age between the late teens and relatively old age (Wills) The patients are usually emaciated edema may be present the neurological manifestations are absent The exact cause of the condition is not clear but it probably is due to absence in the diet of some factor necessary for the normal rate of formation of red blood cells in the bone marrow It

the greatest therapeutic problem since the introduction of liver therapy and it is easily the most important single factor in estimating the prognosis Approximately 85 per cent of our patients showed improvement in their neurologic manifestations when *treated efficiently* with a refined, concentrated liver extract intramuscularly and in only 2 per cent was there an advance in the symptoms On the other hand only 28 6 per cent of the patients in whom the treatment had been *inadequate* exhibited improvement, and 28 5 per cent showed an unfavorable progression

It is of great importance from the standpoint of prognosis to consider the extent and duration of the neurologic lesions Often these have the same meaning that is the longer the duration the greater the extent of the changes But this is not necessarily true as for example an extensive subacute combined degeneration may develop within a few weeks or sometimes paresthesias of the extremities may be the only evidence of involvement of the nervous system for several years In general after they have been present for more than one year it is agreed that there is a decreased prospect of improvement although it is believed by some that they may diminish in severity even after they have been present for as long as four years

Although it is agreed that a high degree of functional recovery may occur even when the pathologic changes are extensive it must be kept in mind that there is some correlation between the magnitude of the neurologic lesions and the prognosis Thus patients with paresthesias and posterior column spinal cord changes have a less favorable outlook than those without neurologic symptoms or with paresthesias only Those with combined degeneration of the spinal cord especially when they are associated with functional impairment of the urinary bladder usually survive the shortest period of time The characteristic course of events in patients with bladder complaints leading to a fatal termination is as follows retention of urine with distention of the bladder which invariably leads to a cystitis and eventually an ascending infection of the urinary tract Abscesses of the kidney with septicemia and death due to a complicating bronchopneumonia may follow These changes pertain to the course of the disease in the average patient It should be remembered however, that there have been some remarkable instances of long period of survival of patients with advanced spinal cord changes

*Treatment of Pernicious Anemia and Other Macrocytic Anemias* —The most effective treatment of pernicious anemia is by intramuscular injection of a refined U S P liver extract containing 15 units per cc Treatment with vitamin $B_{12}$ however may prove equally effective Both are complete treatments, that is they favorably affect the anemia the glossitis and the neurological manifestations

A patient with the disorder in relapse should be given intramuscularly daily for one week 1 cc of refined liver extract containing 15 units * The same dosage is continued three times weekly for the next two weeks and thereafter twice weekly When the hemoglobin reaches 13 grams per 100 cc of blood and the red blood-cell count 4 5 million per cubic millimeter a maintenance dosage is given this should be continued throughout the patient s life With refined liver extract the average adequate maintenance dose is 1 cc containing 15 U S P units, given intramuscularly every two weeks or 2 cc containing 30 units given intramuscularly every 4 weeks The dosage of vitamin $B_{12}$ may be estimated on the basis that one microgram of the vitamin equals approximately one unit of liver extract

The first evidence of improvement after antipernicious anemia medication is seen in from three to six days There are a striking increase in appetite a rapid disappearance of gastrointestinal complaints a fall in the body temperature and pulse rate to normal and a gain in strength which often permits the patient to resume normal activities in from four to eight weeks The earliest change in the blood is an increase in the immature red blood cells or reticulo-

* A unit of liver extract is that amount which produces when administered daily a satisfactory clinical and hematopoietic response in Addisonian pernicious anemia

The *megaloblastic anemia of infancy,* characterized by a macrocytic anemia with megaloblastic hyperplasia of the bone marrow, usually occurs in infants under 18 months of age Recovery generally follows therapy with one course of liver extract or folic acid The nervous system is not involved, and there is a marked hypoacidity of the gastric juice, or achlorhydria The outstanding feature of this disease and that which distinguishes it from true Addisonian pernicious anemia is the cure by one course of treatment (there is no relapse despite discontinuance of therapy) The most likely cause is a deficiency of folic acid (Luby and Wheeler, 1949) due to dietary deficiency and the influence of infection, which may decrease the folic acid reserves of the body, lower the intake (by creating anorexia), prevent absorption (by causing diarrhea), and possibly reduce bacterial synthesis of folic acid in the intestinal tract It is suggested by Zuelzer that 20 milligrams of folic acid be given by daily parenteral injections for a week, although doses of as little as 5 milligrams a day given orally have proved adequate Liver extract in doses of 15 USP units or vitamin $B_{12}$ 15 units given parenterally and repeated as often as necessary, apparently yield satisfactory results

The following conditions should be listed as possible causes of a macrocytic anemia and ones which should be considered in the differential diagnosis of pernicious anemia They do not, however cause megaloblastic hyperplasia of the bone marrow but a condition that is either normoblastic or macronormoblastic These conditions in which the red blood cell volume (M C V) may be between 96 and 120 cubic microns but rarely exceeds 110 cubic microns, are as follows (1) myelophthisic anemia the most important causes of which are subleukemic leukemia and Hodgkin's disease (2) myxedema (3) hemolytic anemia (4) aplastic anemia and (5) acute hemorrhage Nephritis is sometimes given as a cause of a macrocytic anemia, but this is seldom true The anemia associated with nephritis is normocytic and normochromic

*Prognosis* —Prior to the introduction of modern methods of treatment, pernicious anemia was rightly considered to be an invariably fatal disease from which the average patient succumbed within two to three years In most instances, however there were spontaneous remissions which persisted for three to six months but the general trend of the disease was invariably downward Occasionally a patient survived for five or six years, and rarely as long as fifteen or twenty years

With the introduction of specific anti pernicious anemia therapy, the outlook has been completely changed and, theoretically at least, a patient with proper treatment should live for his normal span of life or die of some unrelated condition Certainly the prognosis is much more promising as indicated by the statistics of the Metropolitan Life Insurance Company, which show that the disease is now responsible for about 7000 fewer deaths a year in the United States than it was 20 years ago and that there has been a decrease of 80 per cent in the death rate as a result of the modern treatment at the ages of 45 to 75 years, where the mortality of the disease is concentrated With additional improvement in specific medications and their methods of administration, constant betterment in the outlook of patients with this disease is to be anticipated

The most important factors in the prognosis are the effectiveness with which the anti pernicious anemia medication is given, the state of the nervous system the occurrence of infections and the fact that an increased dosage is required in older patients or those with arteriosclerotic changes The most common cause for failure is the unnecessary and regrettable tendency of the patient to become lax in taking treatment Usually the ensuing relapse is not complete but it may be of such an extent that the neurologic lesions progress to an irreversible state It is of first importance in combating this to prescribe an amount of medication which is somewhat in excess of the minimal dosage necessary to keep the blood within normal limits and to insist that each patient report at least every three months for a complete blood examination

The nervous system involvement has been

the greatest therapeutic problem since the introduction of liver therapy and it is easily the most important single factor in estimating the prognosis. Approximately 85 per cent of our patients showed improvement in their neurologic manifestations when *treated efficiently* with a refined concentrated liver extract intramuscularly, and in only 2 per cent was there an advance in the symptoms. On the other hand only 28.6 per cent of the patients in whom the treatment had been *inadequate* exhibited improvement, and 28.5 per cent showed an unfavorable progression.

It is of great importance from the standpoint of prognosis to consider the extent and duration of the neurologic lesions. Often these have the same meaning, that is, the longer the duration, the greater the extent of the changes. But this is not necessarily true as, for example, an extensive subacute combined degeneration may develop within a few weeks, or sometimes paresthesias of the extremities may be the only evidence of involvement of the nervous system for several years. In general, after they have been present for more than one year it is agreed that there is a decreased prospect of improvement, although it is believed by some that they may diminish in severity even after they have been present for as long as four years.

Although it is agreed that a high degree of functional recovery may occur even when the pathologic changes are extensive, it must be kept in mind that there is some correlation between the magnitude of the neurologic lesions and the prognosis. Thus patients with paresthesias and posterior column spinal cord changes have a less favorable outlook than those without neurologic symptoms or with paresthesias only. Those with combined degeneration of the spinal cord, especially when they are associated with functional impairment of the urinary bladder, usually survive the shortest period of time. The characteristic course of events in patients with bladder complaints leading to a fatal termination is as follows: retention of urine with distention of the bladder, which invariably leads to a cystitis and eventually an ascending infection of the urinary tract. Abscesses of the kidney with septicemia and death due to a complicating bronchopneumonia may follow. These changes pertain to the course of the disease in the average patient. It should be remembered, however, that there have been some remarkable instances of long period of survival of patients with advanced spinal cord changes.

*Treatment of Pernicious Anemia and Other Macrocytic Anemias.*—The most effective treatment of pernicious anemia is by intramuscular injection of a refined U.S.P. liver extract containing 15 units per cc. Treatment with vitamin $B_{12}$, however, may prove equally effective. Both are complete treatments, that is, they favorably affect the anemia, the glossitis and the neurological manifestations.

A patient with the disorder in relapse should be given intramuscularly daily for one week 1 cc. of refined liver extract containing 15 units.* The same dosage is continued three times weekly for the next two weeks and thereafter twice weekly. When the hemoglobin reaches 13 grams per 100 cc. of blood and the red blood-cell count 4.5 million per cubic millimeter, a maintenance dosage is given; this should be continued throughout the patient's life. With refined liver extract the average adequate maintenance dose is 1 cc. containing 15 U.S.P. units given intramuscularly every two weeks, or 2 cc. containing 30 units given intramuscularly every 4 weeks. The dosage of vitamin $B_{12}$ may be estimated on the basis that one microgram of the vitamin equals approximately one unit of liver extract.

The first evidence of improvement after antipernicious anemia medication is seen in from three to six days. There are a striking increase in appetite, a rapid disappearance of gastrointestinal complaints, a fall in the body temperature and pulse rate to normal, and a gain in strength which often permits the patient to resume normal activities in from four to eight weeks. The earliest change in the blood is an increase in the immature red blood cells or reticulo

* A unit of liver extract is that amount which produces, when administered daily, a satisfactory clinical and hematopoietic response in Addisonian pernicious anemia.

The *megaloblastic anemia of infancy*, characterized by a macrocytic anemia with megaloblastic hyperplasia of the bone marrow, usually occurs in infants under 18 months of age. Recovery generally follows therapy with one course of liver extract or folic acid. The nervous system is not involved and there is a marked hypoacidity of the gastric juice, or achlorhydria. The outstanding feature of this disease and that which distinguishes it from true Addisonian pernicious anemia is the cure by one course of treatment (there is no relapse, despite discontinuance of therapy). The most likely cause is a deficiency of folic acid (Luby and Wheeler, 1949) due to dietary deficiency and the influence of infection, which may decrease the folic acid reserves of the body, lower the intake (by creating anorexia), prevent absorption (by causing diarrhea), and possibly reduce bacterial synthesis of folic acid in the intestinal tract. It is suggested by Zuelzer that 20 milligrams of folic acid be given by daily parenteral injections for a week although doses of as little as 5 milligrams a day given orally have proved adequate. Liver extract in doses of 15 USP units, or vitamin $B_{12}$ 15 units given parenterally and repeated as often as necessary, apparently yield satisfactory results.

The following conditions should be listed as possible causes of a macrocytic anemia and ones which should be considered in the differential diagnosis of pernicious anemia. They do not, however, cause megaloblastic hyperplasia of the bone marrow but a condition that is either normoblastic or macronormoblastic. These conditions in which the red blood cell volume (M.C.V.) may be between 96 and 120 cubic microns but rarely exceeds 110 cubic microns, are as follows: (1) myelophthisic anemia, the most important causes of which are subleukemic leukemia and Hodgkin's disease; (2) myxedema; (3) hemolytic anemia; (4) aplastic anemia; and (5) acute hemorrhage. Nephritis is sometimes given as a cause of a macrocytic anemia but this is seldom true. The anemia associated with nephritis is normocytic and normochromic.

*Prognosis.*—Prior to the introduction of modern methods of treatment pernicious anemia was rightly considered to be an invariably fatal disease from which the average patient succumbed within two to three years. In most instances, however, there were spontaneous remissions which persisted for three to six months but the general trend of the disease was invariably downward. Occasionally a patient survived for five or six years, and rarely as long as fifteen or twenty years.

With the introduction of specific antipernicious anemia therapy the outlook has been completely changed and, theoretically at least, a patient with proper treatment should live for his normal span of life or die of some unrelated condition. Certainly the prognosis is much more promising, as indicated by the statistics of the Metropolitan Life Insurance Company which show that the disease is now responsible for about 7000 fewer deaths a year in the United States than it was 20 years ago and that there has been a decrease of 80 per cent in the death rate as a result of the modern treatment at the ages of 45 to 75 years where the mortality of the disease is concentrated. With additional improvement in specific medications and their methods of administration, constant betterment in the outlook of patients with this disease is to be anticipated.

The most important factors in the prognosis are the effectiveness with which the antipernicious anemia medication is given, the state of the nervous system, the occurrence of infections, and the fact that an increased dosage is required in older patients or those with arteriosclerotic changes. The most common cause for failure is the unnecessary and regrettable tendency of the patient to become lax in taking treatment. Usually the ensuing relapse is not complete but it may be of such an extent that the neurologic lesions progress to an irreversible state. It is of first importance in combating this to prescribe an amount of medication which is somewhat in excess of the minimal dosage necessary to keep the blood within normal limits and to insist that each patient report at least every three months for a complete blood examination.

The nervous system involvement has been

minor) or supply the extra dosage some patients need as they grow older (3) inadequacy of the average dose for the individual patient and (4) development of sensitivity to the therapeutic agent (this occurs in a small but important group of the patients)

To prevent therapeutic failure the patient's blood should be examined regularly as a guide to the amount of medication necessary to maintain the blood in normal condition If an infection develops even one of a mild upper respiratory type the dose should be doubled until the infection has entirely subsided For any patient the possibility that a greater dosage is required with increasing age should be kept in mind

Indications of sensitivity to liver extract are flushing of the face palpitation and tachycardia itching of the skin urticaria stuffiness of the nasal passages occasional frank asthmatic attacks and (though rarely) loss of consciousness The immediate symptoms are usually relieved by the subcutaneous injection of 0 5 cc of 1/1000 solution of epinephrin hydrochloride The simplest permanent solution of this problem is to change the therapy to vitamin $B_1$ which can usually be given with impunity Recently however Young Ulrich and Fouts have reported the case of a patient who showed severe allergic symptoms after the injection of vitamin $B_{12}$ concentrate but did not o react to crystalline vitamin $B_1$ If it is desirable to desensitize the patient to liver extract this may be done by injecting subcutaneously from 0 01 cc to 0 05 cc of a solution containing 15 units per cc and doubling the quantity every half hour until a dose of 1 cc is given Oral liver extract or desiccated stomach or liver stomach preparations for oral use may be employed but they are less effective Since folic acid may harm the nervous system it is not recommended that it be employed

If vitamin $B_{12}$ is used it should be given the patient when he is in relapse The dosage follows 10 micrograms of the crystalline form or 15 U S P units of the concentrate daily for the first week the same amount three times weekly for the second and third weeks and twice weekly thereafter until the blood is normal A maintenance dose is 20 micrograms of the crystalline form or 1 cc containing 15 U S P units of the concentrate given every two weeks Further experience will probably indicate that doubling this dosage and giving it every four weeks will maintain the blood in a normal condition

Though 1 microgram daily may suffice for some patients it is inadequate for others The only safe course to pursue is to examine the blood at intervals to determine accurately whether the dose administered is optimal As much as two single doses of 1000 micrograms each have been given intramuscularly 13 weeks apart to a patient with pernicious anemia and subacute combined degeneration Apparently they caused no ill effects, and improvement in the neurologic manifestations appeared to be more rapid than is usually observed when other methods of treatment are used (Bortz 1950) Further experience with this method of treatment is desirable before it can be recommended for general use

When vitamin $B_{12}$ is administered orally even in doses as great as 250 milligrams the therapeutic results are uncertain It has been shown (Bethell Hall and associates) that the activity of vitamin $B_{12}$ when given orally may be greatly increased if combined with extracts of hog s stomach and duodenum Such preparations are not yet available commercially but they may prove practical for oral treatment in the future

*Folic acid should not be employed in the treatment of patients with pernicious anemia* mainly because it is ineffective in controlling the degenerative lesions in the nervous system in fact some claim that it actually causes a progression of these lesions When folic acid is given orally in doses of 5 milligrams daily it is an unsatisfactory form of maintenance treatment Long term evaluation has shown that a high percentage of the patients will suffer a hematologic or neurologic relapse Larger doses though they should maintain the blood in a normal condition are not advisable for the hazard of neurologic relapse is too great The administration of folic acid to normal persons or patients with anemia other than pernicious anemia does not result in alterations in the nervous system Adverse changes are

cytes which are usually 1 per cent or less in relapse The reticulocyte response is in the form of a curve beginning from two to six days after initiation of treatment reaching a peak between the seventh and ninth days and returning to normal by the fifteenth day The height of the curve varies inversely with the level of the red blood cell count before treatment for example if the count is 1 0 million per cubic millimeter the reticulocyte peak would be about 37 per cent 2 0 million per cubic millimeter, 19 per cent, 3 0 million 6 4 per cent, 3 5 million, 1 8 per cent The average increase in the red blood cell count in the first two weeks of treatment varies from about 200 000 to 400,000 per cubic millimeter per week

A patient treated in accordance with the above directions should do well There are however several possible causes for failure (1) relapse due to lack of co-operation by the patient the most common cause of inefficient treatment, (2) failure to double therapeutic dosage in case of infection (even if only

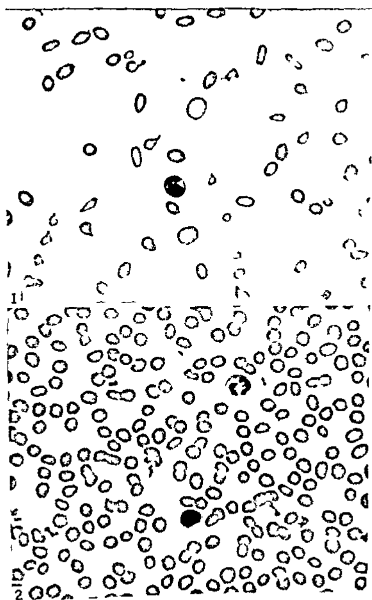

Fig 185 —Change in red cells with specific liver therapy (1) The macrocytosis poikilocytosis and anisocytosis characteristic of pernicious anemia (2) disappeared entirely with adequate treatment (Haden s Principles of Hematology )

minor) or supply the extra dosage some patients need as they grow older (3) inadequacy of the average dose for the individual patient, and (4) development of sensitivity to the therapeutic agent (this occurs in a small but important group of the patients)

To prevent therapeutic failure the patient's blood should be examined regularly as a guide to the amount of medication necessary to maintain the blood in normal condition If an infection develops even one of a mild upper respiratory type the dose should be doubled until the infection has entirely subsided For any patient the possibility that a greater dosage is required with increasing age should be kept in mind

Indications of sensitivity to liver extract are flushing of the face palpitation and tachycardia itching of the skin urticaria stuffiness of the nasal passages occasional frank asthmatic attacks and (though rarely) loss of consciousness The immediate symptoms are usually relieved by the subcutaneous injection of 0 5 cc of 1/1000 solution of epinephrin hydrochloride The simplest permanent solution of this problem is to change the therapy to vitamin $B_{12}$ which can usually be given with impunity Recently however Young Ulrich and Fouts have reported the case of a patient who showed severe allergic symptoms after the injection of vitamin $B_{12}$ concentrate but did not so react to crystalline vitamin $B_{12}$ If it is desirable to desensitize the patient to liver extract this may be done by injecting subcutaneously from 0 01 cc to 0 05 cc of a solution containing 15 units per cc and doubling the quantity every half hour until a dose of 1 cc is given Oral liver extract or desiccated stomach or liver stomach preparations for oral use may be employed but they are less effective Since folic acid may harm the nervous system it is not recommended that it be employed

If vitamin $B_{12}$ is used it should be given the patient when he is in relapse The dosage follows 10 micrograms of the crystalline form or 15 U S P units of the concentrate, daily for the first week the same amount three times weekly for the second and third weeks and twice weekly thereafter until the blood is normal A maintenance dose is 20 micrograms of the crystalline form or 1 cc containing 15 U S P units of the concentrate given every two weeks Further experience will probably indicate that doubling this dosage and giving it every four weeks will maintain the blood in a normal condition

Though 1 microgram daily may suffice for some patients it is inadequate for others The only safe course to pursue is to examine the blood at intervals to determine accurately whether the dose administered is optimal As much as two single doses of 1000 micrograms each have been given intramuscularly 13 weeks apart to a patient with pernicious anemia and subacute combined degeneration Apparently they caused no ill effects and improvement in the neurologic manifestations appeared to be more rapid than is usually observed when other methods of treatment are used (Bortz 1950) Further experience with this method of treatment is desirable before it can be recommended for general use

When vitamin $B_{12}$ is administered orally even in doses as great as 250 milligrams the therapeutic results are uncertain It has been shown (Bethell Hall and associates) that the activity of vitamin $B_{12}$ when given orally may be greatly increased if combined with extracts of hog's stomach and duodenum Such preparations are not yet available commercially but they may prove practical for oral treatment in the future

*Folic acid should not be employed in the treatment of patients with pernicious anemia* mainly because it is ineffective in controlling the degenerative lesions in the nervous system in fact some claim that it actually causes a progression of these lesions When folic acid is given orally in doses of 5 milligrams daily it is an unsatisfactory form of maintenance treatment Long term evaluation has shown that a high percentage of the patients will suffer a hematologic or neurologic relapse Larger doses though they should maintain the blood in a normal condition are not advisable for the hazard of neurologic relapse is too great The administration of folic acid to normal persons or patients with anemia other than pernicious anemia does not result in alterations in the nervous system Adverse changes are

not produced in the nervous system by the drug in cases of sprue. It seems clear, therefore, that folic acid does not have a toxic effect on the nervous system of persons who do not have pernicious anemia. The possibility, however, that it may cause injury in patients with a macrocytic anemia associated with total gastrectomy or other gastrointestinal disturbances must be kept in mind.

Folic acid is a satisfactory form of therapy, however, in the macrocytic anemia of pregnancy, in some forms of nutritional anemia such as sprue, idiopathic steatorrhea, and coeliac disease, in anemia due to intestinal stenosis or associated with "short circuiting" operations on the gastro intestinal tract, in megaloblastic anemia of infancy, and sometimes, in the macrocytic anemia occasionally observed in patients with cirrhosis of the liver. Occasionally, when folic acid is given intravenously, there may be unpleasant minor vasomotor symptoms such as flushing of the face and tingling of the extremities. One severe anaphylactoid reaction is reported (Mitchell, 1949).

The oral treatment of pernicious anemia is less reliable than the parenteral. Ventriculin (desiccated, defatted hog stomach) may be used in doses of 40 grams daily in cases of relapse and in doses of 20 grams daily as a maintenance dose. Liver-extract powder for oral use may be given in doses of 12.75 grams daily (3 level teaspoonfuls) or "Extralin," which is a liver-stomach concentrate, may be employed in a maintenance dose of four pulvules (2 grams) daily.

Other types of therapy used in pernicious anemia are of secondary minor importance. *Blood transfusions* are indicated only if the condition of the patient is precarious and there is a possibility that death may occur before the antipernicious anemia medication takes effect. *Iron medication* is ordinarily not indicated. If the mean corpuscular hemoglobin concentration and the color index remain persistently low, however, ferrous sulfate should be given in doses of 0.3 grams t.i.d. a.c. In my experience, *dilute hydrochloric acid* is not of value in the treatment of this disorder. The gastrointestinal symptoms usually disappear with the proper antipernicious anemia medication, if they do not, some complication, such as cancer of the stomach or gall bladder disease, should be suspected. Rarely is it necessary to correct the *diet or add supplementary vitamins*. This is because, with the proper treatment, a wide variety of foods is usually consumed in large amounts. In each patient, however, the possibility of a dietary deficiency should be kept in mind if the blood does not return to normal or complaints persist. *Constipation* is commonly associated, but this is usually regulated with increased activity and a more complete diet as the blood improves. Cascara sagrada usually suffices alone or with liquid petrolatum, if constipation persists. Fecal impaction should be kept in mind in patients with far advanced spinal cord changes. As soon as the patients show improvement in the blood, they are encouraged to *exercise* moderately in accordance with their general strength, the condition of their blood, and their neurologic involvement. Carefully regulated active exercises are superior to passive motion in improving the status of the changes incident to the neurologic condition. There is no indication that crude liver extracts or added vitamins are beneficial in the treatment of changes in the nervous system.

Patients with advanced neurological changes and inability to control the bladder require special care. In some cases it is advisable to introduce an inlying catheter and employ either sulamyd in doses of 0.5 grams 4 t.i.d. or appropriate antibiotic therapy.

## HEMOLYTIC ANEMIA

By RUSSELL L HADEN M D

A hemolytic anemia is one due to a more rapid destruction of erythrocytes than the bone marrow can replace Normally a close balance is maintained between red cell formation and loss If hemolysis is excessive from any cause anemia results

Every normal red blood cell wears out after circulating on the average for 120 days It is removed by reticulo-endothelial cells mostly in the spleen The stroma disintegrates the hemoglobin is split up the iron is set free and bilirubin is formed The bilirubin is bound to protein and tends to remain in the plasma hence the amount of bilirubin present is an indirect measure of the rate of red cell destruction

With excessive loss of erythrocytes the bone marrow attempts to compensate by a higher rate of delivery of cells The bone marrow on examination is hyperplastic with an excessive number of young red cells Since many of the circulating red cells are young they appear as reticulocytes The reticulocyte count is a measure of the rate at which new cells are delivered from the bone marrow An elevated reticulocyte count in the peripheral blood is thus typical of a hemolytic anemia with active marrow

The spleen is overactive in removing abnormal and dying cells from the circulation it is usually enlarged in a hemolytic anemia

Clinically, one sees jaundice and an enlarged spleen in hemolytic anemia In the laboratory one finds a reduction in red cells and hemoglobin an increased reticulocyte count and an increased bilirubin content in the plasma The bone marrow shows excessive erythropoiesis with many normoblasts and erythroblasts

Accelerated hemolysis may be due to agents toxic for the erythrocyte in the blood plasma such as

1) Toxins resulting from bacterial growth
2) Isohemolysins which cause hemolysis when a patient is transfused with an incompatible blood type In acquired hemolytic anemia there may be immune hemolysins This is also the mechanism of the hemolysis in erythroblastosis
3) Chemical poisons such as phenylhydrazine Many other chemical substances will actively destroy red cells—among these are bile salts saponin and snake venoms Intracellular parasites such as those of malaria obviously damage cells in which they are contained

Increased hemolysis may also result from the abnormal shape of a red cell or a qualitative defect in the stroma In hereditary spherocytosis (familial hemolytic jaundice) the basis for the rapid red-cell destruction seems to be the shape (spheroidal) of the erythrocyte Both Mediterranean anemia (Cooley s anemia) and sickle cell anemia stem from a hereditary defect in the stroma or hemoglobin this accelerates hemolysis and produces a hemolytic anemia Rarely abnormal hemolysis seems to be due to a perverted activity of the reticulo-endothelial cells especially in the spleen

*Classification of Hemolytic Anemia* —There are numerous classifications of hemolytic anemia A simple one follows

I Increased hemolysis from excessive destruction of cells damaged by
 1) chemical agents (like phenylhydrazine),
 2) bacterial toxins (as in gas gangrene)
 3) iso hemolysins (as in incompatible blood groups) or immuno hemolysins (as in erythroblastosis)
 4) parasites (as in malaria)
II Increased hemolysis due to excessive removal of red cells abnormal at birth

not produced in the nervous system by the drug in cases of sprue. It seems clear, therefore, that folic acid does not have a toxic effect on the nervous system of persons who do not have pernicious anemia. The possibility, however, that it may cause injury in patients with a macrocytic anemia associated with total gastrectomy or other gastrointestinal disturbances must be kept in mind.

Folic acid is a satisfactory form of therapy, however, in the macrocytic anemia of pregnancy, in some forms of nutritional anemia such as sprue, idiopathic steatorrhea and coeliac disease, in anemia due to intestinal stenosis or associated with "short circuiting" operations on the gastro-intestinal tract, in megaloblastic anemia of infancy and, sometimes, in the macrocytic anemia occasionally observed in patients with cirrhosis of the liver. Occasionally, when folic acid is given intravenously, there may be unpleasant minor vasomotor symptoms, such as flushing of the face and tingling of the extremities. One severe anaphylactoid reaction is reported (Mitchell, 1949).

The oral treatment of pernicious anemia is less reliable than the parenteral. Ventriculin (desiccated defatted hog stomach) may be used in doses of 40 grams daily in cases of relapse and in doses of 20 grams daily as a maintenance dose. Liver-extract powder for oral use may be given in doses of 12.75 grams daily (3 level teaspoonfuls) or "Extralin," which is a liver stomach concentrate, may be employed in a maintenance dose of four pulvules (2 grams) daily.

Other types of therapy used in pernicious anemia are of secondary minor importance. *Blood transfusions* are indicated only if the condition of the patient is precarious and there is a possibility that death may occur before the antipernicious anemia medication takes effect. *Iron medication* is ordinarily not indicated. If the mean corpuscular hemoglobin concentration and the color index remain persistently low, however, ferrous sulfate should be given in doses of 0.3 grams t.i.d. a.c. In my experience *dilute hydrochloric acid* is not of value in the treatment of this disorder. The gastrointestinal symptoms usually disappear with the proper antipernicious anemia medication; if they do not, some complication, such as cancer of the stomach or gall bladder disease, should be suspected. Rarely is it necessary to correct the *diet or add supplementary vitamins*. This is because, with the proper treatment, a wide variety of foods is usually consumed in large amounts. In each patient, however, the possibility of a dietary deficiency should be kept in mind if the blood does not return to normal or complaints persist. *Constipation* is commonly associated, but this is usually regulated with increased activity and a more complete diet as the blood improves. Cascara sagrada usually suffices, alone or with liquid petrolatum, if constipation persists. Fecal impaction should be kept in mind in patients with far-advanced spinal cord changes. As soon as the patients show improvement in the blood, they are encouraged to *exercise* moderately in accordance with their general strength, the condition of their blood and their neurologic involvement. Carefully regulated active exercises are superior to passive motion in improving the status of the changes incident to the neurologic condition. There is no indication that crude liver extracts or added vitamins are beneficial in the treatment of changes in the nervous system.

Patients with advanced neurological changes and inability to control the bladder require special care. In some cases it is advisable to introduce an inlying catheter and employ either sulamyd in doses of 0.5 grams 4 t.i.d. or appropriate antibiotic therapy.

## HEMOLYTIC ANEMIA

By RUSSELL L HADEN M D

A hemolytic anemia is one due to a more rapid destruction of erythrocytes than the bone marrow can replace Normally a close balance is maintained between red cell formation and loss If hemolysis is excessive from any cause anemia results

Every normal red blood cell wears out after circulating on the average, for 120 days It is removed by reticulo-endothelial cells mostly in the spleen The stroma disintegrates the hemoglobin is split up the iron is set free and bilirubin is formed The bilirubin is bound to protein and tends to remain in the plasma, hence the amount of bilirubin present is an indirect measure of the rate of red cell destruction

With excessive loss of erythrocytes the bone marrow attempts to compensate by a higher rate of delivery of cells The bone marrow on examination is hyperplastic with an excessive number of young red cells Since many of the circulating red cells are young they appear as reticulocytes The reticulocyte count is a measure of the rate at which new cells are delivered from the bone marrow An elevated reticulocyte count in the peripheral blood is thus typical of a hemolytic anemia with active marrow

The spleen is overactive in removing abnormal and dying cells from the circulation it is usually enlarged in a hemolytic anemia

Clinically, one sees jaundice and an enlarged spleen in hemolytic anemia In the laboratory, one finds a reduction in red cells and hemoglobin an increased reticulocyte count, and an increased bilirubin content in the plasma The bone marrow shows excessive erythropoiesis with many normoblasts and erythroblasts

Accelerated hemolysis may be due to agents toxic for the erythrocyte in the blood plasma such as

1) Toxins resulting from bacterial growth
2) Isohemolysins which cause hemolysis when a patient is transfused with an incompatible blood type In acquired hemolytic anemia there may be immune hemolysins This is also the mechanism of the hemolysis in erythroblastosis
3) Chemical poisons such as phenylhydrazine Many other chemical substances will actively destroy red cells—among these are bile salts, saponin and snake venoms Intracellular parasites such as those of malaria obviously damage cells in which they are contained

Increased hemolysis may also result from the abnormal shape of a red cell or a qualitative defect in the stroma In hereditary spherocytosis (familial hemolytic jaundice), the basis for the rapid red-cell destruction seems to be the shape (spheroidal) of the erythrocyte Both Mediterranean anemia (Cooley s anemia) and sickle cell anemia stem from a hereditary defect in the stroma or hemoglobin this accelerates hemolysis and produces a hemolytic anemia Rarely abnormal hemolysis seems to be due to a perverted activity of the reticulo-endothelial cells especially in the spleen

*Classification of Hemolytic Anemia* —There are numerous classifications of hemolytic anemia A simple one follows

I Increased hemolysis from excessive destruction of cells damaged by
   1) chemical agents (like phenylhydrazine)
   2) bacterial toxins (as in gas gangrene)
   3) iso hemolysins (as in incompatible blood groups) or immuno hemolysins (as in erythroblastosis)
   4) parasites (as in malaria)

II Increased hemolysis due to excessive removal of red cells abnormal at birth

not produced in the nervous system by the drug in cases of sprue It seems clear therefore that folic acid does not have a toxic effect on the nervous system of persons who do not have pernicious anemia The possibility however, that it may cause injury in patients with a macrocytic anemia associated with total gastrectomy or other gastrointestinal disturbances must be kept in mind

Folic acid is a satisfactory form of therapy, however in the macrocytic anemia of pregnancy in some forms of nutritional anemia such as sprue idiopathic steatorrhea, and coeliac disease, in anemia due to intestinal stenosis or associated with "short circuiting" operations on the gastro intestinal tract in megaloblastic anemia of infancy and, sometimes in the macrocytic anemia occasionally observed in patients with cirrhosis of the liver Occasionally when folic acid is given intravenously, there may be unpleasant minor vasomotor symptoms, such as flushing of the face and tingling of the extremities One severe anaphylactoid reaction is reported (Mitchell 1949)

The oral treatment of pernicious anemia is less reliable than the parenteral Ventriculin (desiccated, defatted hog stomach) may be used in doses of 40 grams daily in cases of relapse and in doses of 20 grams daily as a maintenance dose Liver-extract powder for oral use may be given in doses of 12 75 grams daily (3 level teaspoonfuls), or "Extralin," which is a liver stomach concentrate may be employed in a maintenance dose of four pulvules (2 grams) daily

Other types of therapy used in pernicious anemia are of secondary minor importance *Blood transfusions* are indicated only if the condition of the patient is precarious and there is a possibility that death may occur before the antipernicious anemia medication takes effect *Iron medication* is ordinarily not indicated If the mean corpuscular-hemoglobin concentration and the color index remain persistently low however ferrous sulfate should be given in doses of 0 3 grams t i d, a c In my experience *dilute hydrochloric acid* is not of value in the treatment of this disorder The gastrointestinal symptoms usually disappear with the proper antipernicious anemia medication, if they do not, some complication, such as cancer of the stomach or gall bladder disease, should be suspected Rarely is it necessary to correct the *diet or add supplementary vitamins* This is because with the proper treatment, a wide variety of foods is usually consumed in large amounts In each patient, however, the possibility of a dietary deficiency should be kept in mind if the blood does not return to normal or complaints persist *Constipation* is commonly associated but this is usually regulated with increased activity and a more complete diet as the blood improves Cascara sagrada usually suffices, alone or with liquid petrolatum, if constipation persists Fecal impaction should be kept in mind in patients with far advanced spinal cord changes As soon as the patients show improvement in the blood they are encouraged to *exercise* moderately in accordance with their general strength the condition of their blood, and their neurologic involvement Carefully regulated active exercises are superior to passive motion in improving the status of the changes incident to the neurologic condition There is no indication that crude liver extracts or added vitamins are beneficial in the treatment of changes in the nervous system

Patients with advanced neurological changes and inability to control the bladder require special care In some cases it is advisable to introduce an inlying catheter and employ either sulamyd in doses of 0 5 grams 4 t i d or appropriate antibiotic therapy

## HEMOLYTIC ANEMIA

By Russell L Haden M D

A hemolytic anemia is one due to a more rapid destruction of erythrocytes than the bone marrow can replace Normally a close balance is maintained between red cell formation and loss If hemolysis is excessive from any cause anemia results

Every normal red blood cell wears out after circulating on the average, for 120 days It is removed by reticulo-endothelial cells mostly in the spleen The stroma disintegrates the hemoglobin is split up the iron is set free and bilirubin is formed The bilirubin is bound to protein and tends to remain in the plasma hence the amount of bilirubin present is an indirect measure of the rate of red cell destruction

With excessive loss of erythrocytes the bone marrow attempts to compensate by a higher rate of delivery of cells The bone marrow on examination is hyperplastic with an excessive number of young red cells Since many of the circulating red cells are young they appear as reticulocytes The reticulocyte count is a measure of the rate at which new cells are delivered from the bone marrow An elevated reticulocyte count in the peripheral blood is thus typical of a hemolytic anemia with active marrow

The spleen is overactive in removing abnormal and dying cells from the circulation it is usually enlarged in a hemolytic anemia

Clinically, one sees jaundice and an enlarged spleen in hemolytic anemia In the laboratory one finds a reduction in red cells and hemoglobin, an increased reticulocyte count and an increased bilirubin content in the plasma The bone marrow shows excessive erythropoiesis with many normoblasts and erythroblasts

Accelerated hemolysis may be due to agents toxic for the erythrocyte in the blood plasma such as

1) Toxins resulting from bacterial growth
2) Isohemolysins which cause hemolysis when a patient is transfused with an incompatible blood type In acquired hemolytic anemia there may be immune hemolysins This is also the mechanism of the hemolysis in erythroblastosis
3) Chemical poisons such as phenylhydrazine Many other chemical substances will actively destroy red cells—among these are bile salts saponin and snake venoms Intracellular parasites such as those of malaria obviously damage cells in which they are contained

Increased hemolysis may also result from the abnormal shape of a red cell or a qualitative defect in the stroma In hereditary spherocytosis (familial hemolytic jaundice) the basis for the rapid red-cell destruction seems to be the shape (spheroidal) of the erythrocyte Both Mediterranean anemia (Cooley s anemia) and sickle cell anemia stem from a hereditary defect in the stroma or hemoglobin this accelerates hemolysis and produces a hemolytic anemia Rarely, abnormal hemolysis seems to be due to a perverted activity of the reticulo-endothelial cells especially in the spleen

*Classification of Hemolytic Anemia* —There are numerous classifications of hemolytic anemia A simple one follows

I Increased hemolysis from excessive destruction of cells damaged by
   1) chemical agents (like phenylhydrazine)
   2) bacterial toxins (as in gas gangrene)
   3) iso-hemolysins (as in incompatible blood groups) or immuno hemolysins (as in erythroblastosis)
   4) parasites (as in malaria)

II Increased hemolysis due to excessive removal of red cells abnormal at birth

1) spherocytic anemia (familial hemolytic jaundice),
2) sickle cell anemia,
3) oval cell anemia,
4) Mediterranean anemia (Cooley's anemia)

III Increased hemolysis of undetermined cause (immune hemolysins, overactivity of spleen and other parts of reticulo-endothelial system qualitative defect in stroma or hemoglobin, etc)

The complete clinical and laboratory picture of a hemolytic anemia from any cause is as follows jaundice due to increased bilirubin content of the plasma reduction in red cells and hemoglobin increase in reticulocytes enlargement of the spleen and erythrocyte hyperplasia in the marrow The differential diagnosis depends also on a careful clinical and laboratory study In all hemolytic anemias the size and shape of the red cell should be determined In hereditary spherocytosis the red cells show decreased diameter and increased thickness with increased fragility in hypotonic salt solution in sickle cell anemia the cells become sickle-shaped under aerobic conditions in Cooley s anemia there are numerous target cells usually an increase in the number of nucleated cells and decreased fragility of the red cells in hypotonic salt solutions In all hemolytic anemias, there is reticulocytosis of varying degree in the peripheral blood and the bone marrow constantly shows erythroid hyperplasia

A Coombs antiglobulin test should be made in all cases of hemolytic anemia This test detects antibodies which may be responsible for hemolysins in acquired hemolytic anemia Antiglobulin serum made by injecting a rabbit with normal human serum is mixed with washed red cells from hemolytic anemia Clumping of the red cells indicates a positive reaction to the test

## HEREDITARY SPHEROCYTOSIS

*Synonyms* —Congenital hemolytic jaundice, chronic acholuric jaundice familial hemolytic jaundice

*Definition* —Hereditary spherocytosis is a chronic hemolytic anemia characterized by nonobstructive jaundice, spherocytosis increased hypotonic fragility of the red cells reticulocytosis and splenomegaly There may be hemolytic crises

*Etiology* —It is accepted that spherocytosis or a change in the shape of the erythrocytes from biconcave (normal) to spherical or at least an increase in the thickness of the erythrocytes is a constant finding in the disease

Furthermore it is agreed that this alteration in shape accounts for the increased fragility of the cells as it is the first stage of hemolysis As I have written on another occasion The more spherocytic the cell the nearer it is to the hemolysis point When such an alteration exists the reticulo endothelial cells of the spleen and other organs remove the abnormal cells from the circulation at a more rapid rate than erythrocytes can be produced in the marrow, the result is an anemia The immediate cause, therefore, of the anemia is hyperactivity of the spleen but it should be emphasized that the spherocytosis which is the fundamental fault persists after splenectomy

All the major clinical manifestations of the disease are due to the excessive red cell destruction The jaundice is associated with increased production of bile pigment the splenomegaly results from the augmented activity of the spleen in removing erythrocytes from the circulation the reticulocytosis is evidence of the accelerated production and delivery of red cells

There are two views concerning the cause of the spherocytosis and the increased fragility of the erythrocytes One is that the inherited defect is the abnormal shape of the cells and that the immediate cause of the anemia is the hyperactivity of the spleen with rapid removal of many of these cells from the circulation The other view is that these changes are not inborn errors of erythrocyte formation but are the effect of extrinsic agents acting on the cell during its life in the blood stream According to this theory the spherocytosis, increased erythrocyte fragility reticulocytosis and response to splenectomy are not pathognomonic of congenital hemolytic anemia but may also characterize the acquired type of

the anemia and be produced experimentally Such changes are attributed to the effects of a lytic agent on the normal mature red cells

The victim of the disease often has a history of the disease in several previous generations of his family but the condition may have been so mild in some of his predecessors as to go unrecognized Spherocytosis is transmitted by the two sexes as a Mendelian dominant trait and occurs with equal frequency in both adult life although they may be so mild as to be overlooked For this reason it cannot be said that other cases do not exist in a patient's family unless the patient s relatives have been examined The jaundice is usually very slight except during crisis It has often been said that the patients are "more yellow than sick" as no other complaints may be present The crisis of the disease to which any patient is liable are characterized by fever malaise abdominal pain nausea and vomiting intensification of the jaundice and

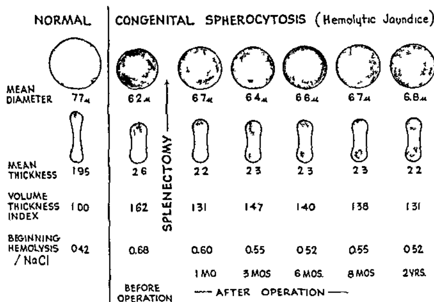

FIG 186 —Chart to show the shape of cells in patient with congenital hemolytic jaundice and effect of splenectomy (Haden s Principles of Hematology )

*Pathology* —There is marked congestion of the spleen which involves the pulp but not the sinuses the organ is enlarged often weighing from 1000 to 1500 grams Ordinarily it is not adherent, in contrast to the spleen in Banti s disease and is easily removed The endothelial cells of the spleen liver bone marrow, and lymph nodes (reticulo-endothelial system) show evidence of activity as indicated by phagocytosis of red blood cells and pigment The liver kidneys and lymph glands have the changes of hemosiderosis Gallstones composed largely of bilirubin are frequently found

*Symptoms and Signs* —Evidences of the disease usually appear in childhood or young a rapid fall in the red blood cell count Cholelithiasis due to increased formation of bile pigments is frequently present Leg ulcers may occur but are uncommon The spleen is palpable in about 75 per cent of the patients but is seldom greatly enlarged it is not common to observe a liver which is significantly increased in size—indeed gross hepatomegaly casts considerable suspicion on the diagnosis Developmental anomalies may occur especially the tower skull ( turmschadel ) A number of others have been reported such as prominent eyes an abnormally wide root of the nose and changes in the teeth On roentgen examination the frontal and

parietal bones may show thickening and striations.

The diagnosis is certain in the presence of hemolytic anemia of familial origin, reticulocytosis, spherocytosis, increased fragility of the erythrocytes, splenomegaly, and nonobstructive jaundice.

*Blood Examination.*—There is commonly a red blood cell count which varies between 2,000,000 and 3,500,000 per c.mm.; the average hemoglobin reading is between 40 and 70 per cent. The color index is most frequently about 1. During spontaneous remissions the red cell count may be normal, whereas in crises it may fall to 1,000,000 per c.mm. or less. The average volume of the cells is somewhat decreased, most commonly varying between 75 and 85 cubic microns, although it may be normal or even increased. The mean erythrocyte diameter is reduced, measuring between 6.2 and 7 microns. The increased thickness of the cells, averaging 2.2 to 3.4 microns instead of the normal of 2 microns or less, is due to the diminished mean cell diameter in association with a normal or only slightly reduced mean corpuscular volume. There is some anisocytosis, but poikilocytosis is not common. Nucleated red blood cells and polychromatophilic cells are frequently present. Ordinarily there are no important changes in the leukocytes or platelets, but in crises the former may be increased. The reticulocytes frequently reach a level between 10 and 15 per cent, and in some patients there may be a very much greater increase. There is usually a decreased resistance of the red blood cells in hypotonic salt solution. Normal red blood cells show hemolysis which begins at 0.44 to 0.48 per cent and is complete at 0.3. In hemolytic jaundice hemolysis may begin at 0.51 to 0.72 per cent and be complete at 0.4 per cent.

The bone marrow shows evidence of increased erythropoietic activity as indicated by hyperplasia of the normoblastic type. These cells make up from 25 to 50 per cent of all nucleated cells; mitosis is common.

*Prognosis and Course of the Disease.*—Victims of spherocytosis often live for years without serious symptoms and may even reach an advanced age. It is characteristic, however, for exacerbations of symptoms to occur, the so-called "crises," at which times persistent vomiting, fever, and abdominal pain occur. Intensification of the jaundice and rapid development of a severe anemia also occur. One of the more distressing complications is the frequently associated cholelithiasis, which results in typical attacks of biliary colic.

*Treatment and Prognosis.*—Splenectomy removes all signs and symptoms of the congenital hemolytic jaundice except spherocytosis. As soon as the diagnosis is proved splenectomy should be performed. The anemia is variable, but even with a mild anemia beginning in childhood the patient is seldom well, growth is often retarded, and resistance to infection is low. It is best to do the splenectomy early. The mortality from operation is almost nil since the spleen is seldom very large and almost never shows adhesions. Infants less than a year old stand the operation well.

Even in mild cases, if splenectomy is not performed, gallstones frequently develop. These in turn may cause colic or lead to cholecystitis.

After splenectomy the jaundice should disappear, and the bilirubin content of the plasma should return to normal and the reticulocyte count become less than 1 per cent within 10 days. Spherocytosis persists. If the operation is not successful, the presence of accessory spleens should be suspected or the possibility of an incorrect diagnosis should be considered. There is usually a rapid rise in the red cells and the hemoglobin. Transfusions are seldom necessary and are best avoided. The usual therapeutic agents, such as iron, arsenic, liver and liver substitutes, are of no value.

## OVALOCYTOSIS

In ovalocytosis, a hereditary blood anomaly transmitted by either sex possibly as a Mendelian dominant trait from 50 to 90 per cent of all circulating erythrocytes may be oval or elliptical in shape The condition is not limited to any race It bears no relationship to "sickling" as no alteration in the shape of these cells occurs in sealed fresh blood preparations Persons with such cells usually do not have an anemia or evidence of excessive red blood-cell destruction It is stated that the mean corpuscular volume may be reduced In such cases the hematocrit reading may be normal if the red cell count is increased above normal

## SICKLE CELL ANEMIA

*Synonyms* —Sicklocytosis meniscocytosis drepanocytic anemia Herrick s syndrome

*Definition* —Sickle cell anemia is a chronic hereditary and familial hemolytic anemia confined with few exceptions to negroes It is due to an intrinsic defect in the erythrocytes and is characterized by the appearance of a considerable number of sickle shaped red cells in the circulating blood the symptoms of an anemia recurrent leg ulcers cardiovascular manifestations and episodes of abdominal pain slight jaundice nausea and vomiting

*Etiology and Pathology* —The disease probably exists from birth as it is usually seen in children although it is observed at all ages It is probably transmitted as a Mendelian dominant characteristic The condition is characterized by periods of activity and quiescence About 7 per cent of all negroe have the sickle cell trait although evidence of anemia appears in only 1 in 40 whose red cells sickle It is generally agreed that sickling is due to a hereditary defect and that the change in shape is an inherent property of the erythrocytes Recently Pauling Itano Singer and Wells have suggested that the hemoglobin in sickle cell anemia has a molecular structure that may be responsible for the shape of the cell Persons with the trait show no characteristic cells on the stained smear but such cells will usually appear in a sealed preparation made from blood obtained from the finger in which stasis has been produced by constriction with a rubber band for five minutes The difference between sickle cell anemia and the sickle cell trait is not clear it may be only that in the anemia the erythrocytes have a greater tendency to undergo changes in shape The explanation of the hemolysis and of the periodic attacks in which it is excessive, is unknown At necropsy fatty degenerative changes and hemosiderosis are found The bone marrow is hyperplastic and contains many nucleated red cells chiefly normoblasts it does not differ from the marrow observed in any type of hemolytic anemia except for the presence of sickle cells Throughout the body but especially in the spleen there are evidences of thrombosis infarction necrosis and hemorrhage The spleen, enlarged and congested in the earlier stage of the disease becomes fibrotic and very small According to Rich the characteristic microscopic findings in this organ are malformation of the splenic sinuses in the immediate vicinity of the Malpighian follicles and collections of pools of blood in fibrosed and atrophic areas The small and medium sized arteries may have thickened walls and show proliferation of the intimal cells Thrombosis of small vessels may cause lesions of the nervous system

*Symptoms* —Even with a moderately advanced anemia the patient may be free from symptoms except for quickness of fatigue Commonly however the patient complains of anemia and a slight jaundice The active symptoms of the disease are attacks of abdominal pain nausea vomiting and moderate jaundice Sometimes the pain may be sharp and this with the associated fever nausea and vomiting and leukocytosis suggests an acute condition requiring surgery Additional symptoms are headache malaise and pain in the muscles and joints symptoms usually associated with a moderate febrile reaction Remarkable features of the disease are the leg ulcers and the cardiac involvement Characteristically the ulcers occur about the ankles average 1 to 3 cm in diameter and have sharp edges with a "punched-out" appearance like luetic ulcers In a fair pro

parietal bones may show thickening and striations

The diagnosis is certain in the presence of hemolytic anemia of familial origin, reticulocytosis spherocytosis increased fragility of the erythrocytes splenomegaly, and nonobstructive jaundice

*Blood Examination* — There is commonly a red blood cell count which varies between 2 000,000 and 3,500 000 per c mm the average hemoglobin reading is between 40 and 70 per cent The color index is most frequently about 1 During spontaneous remissions the red cell count may be normal whereas in crises it may fall to 1 000 000 per c mm or less The average volume of the cells is somewhat decreased most commonly varying between 75 and 85 cubic microns although it may be normal or even increased The mean erythrocyte diameter is reduced measuring between 6 2 and 7 microns The increased thickness of the cells averaging 2 2 to 3 4 microns instead of the normal of 2 microns or less is due to the diminished mean cell diameter in association with a normal or only slightly reduced mean corpuscular volume There is some anisocytosis but poikilocytosis is not common Nucleated red blood cells and polychromatophilic cells are frequently present Ordinarily there are no important changes in the leukocytes or platelets but in crises the former may be increased The reticulocytes frequently reach a level between 10 and 15 per cent and in some patients there may be a very much greater increase There is usually a decreased resistance of the red blood cells in hypotonic salt solution Normal red blood cells show hemolysis which begins at 0 44 to 0 48 per cent and is complete at 0 3 In hemolytic jaundice hemolysis may begin at 0 51 to 0 72 per cent and be complete at 0 4 per cent

The bone marrow shows evidence of increased erythropoietic activity as indicated by hyperplasia of the normoblastic type These cells make up from 25 to 50 per cent of all nucleated cells mitosis is common

*Prognosis and Course of the Disease* — Victims of spherocytosis often live for years without serious symptoms and may even reach an advanced age It is characteristic however for exacerbations of symptoms to occur the so-called 'crises at which times persistent vomiting fever, and abdominal pain occur Intensification of the jaundice and rapid development of a severe anemia also occur One of the more distressing complications is the frequently associated cholelithiasis, which results in typical attacks of biliary colic

*Synonyms* —Sicklocytosis meniscocytosis drepanocytic anemia Herrick s syndrome

*Definition* —Sickle cell anemia is a chronic hereditary and familial hemolytic anemia confined with few exceptions to negroes It is due to an intrinsic defect in the erythrocytes and is characterized by the appearance of a considerable number of sickle shaped red cells in the circulating blood the symptoms of an anemia recurrent leg ulcers cardiovascular manifestations and episodes of abdominal pain slight jaundice nausea and vomiting

*Etiology and Pathology* —The disease probably exists from birth as it is usually seen in children although it is observed at all ages It is probably transmitted as a Mendelian dominant characteristic The condition is characterized by periods of activity and quiescence About 7 per cent of all negroes have the sickle cell trait although evidence of anemia appears in only 1 in 40 whose red cells sickle It is generally agreed that sickling is due to a hereditary defect and that the change in shape is an inherent property of the erythrocytes Recently Pauling Itano Singer and Wells have suggested that the hemoglobin in sickle cell anemia has a molecular structure that may be responsible for the shape of the cell Persons with the trait show no characteristic cells on the stained smear but such cells will usually appear in a sealed preparation made from blood obtained from the finger in which stasis has been produced by constriction with a rubber band for five minutes The difference between sickle cell anemia and the sickle cell trait is not clear it may be only that in the anemia the erythrocytes have a greater tendency to undergo changes in shape The explanation of the hemolysis and of the periodic attacks in which it is excessive is unknown At necropsy fatty degenerative changes and hemosiderosis are found The bone marrow is hyperplastic and contains many nucleated red cells chiefly normoblasts it does not differ from the marrow observed in any type of hemolytic anemia except for the presence of sickle cells Throughout the body but especially in the spleen there are evidences of thrombosis infarction necrosis, and hemorrhage The spleen enlarged and congested in the earlier stage of the disease becomes fibrotic and very small According to Rich the characteristic microscopic findings in this organ are malformation of the splenic sinuses in the immediate vicinity of the Malpighian follicles and collections of pools of blood in fibrosed and atrophic areas The small and medium-sized arteries may have thickened walls and show proliferation of the intimal cells Thrombosis of small vessels may cause lesions of the nervous system

*Symptoms* —Even with a moderately advanced anemia the patient may be free from symptoms except for quickness of fatigue Commonly however the patient complains of anemia and a slight jaundice The active symptoms of the disease are attacks of abdominal pain nausea vomiting and moderate jaundice Sometimes the pain may be sharp and this, with the associated fever nausea and vomiting and leukocytosis suggests an acute condition requiring surgery Additional symptoms are headache malaise and pain in the muscle and joints symptoms usually associated with a moderate febrile reaction Remarkable features of the disease are the leg ulcers and the cardiac involvement Characteristically the ulcers occur about the ankles average 1 to 3 cm in diameter and have sharp edges with a punched-out appearance like luetic ulcers In a fair pro

portion of the patients, there is definite cardiac hypertrophy, not infrequently there are symptoms of chronic cardiac failure A history of recurrent attacks of painful joints in a young person with an enlarged heart and an apical systolic murmur, sometimes leads to an incorrect diagnosis of rheumatic mitral insufficiency Early in sickle cell anemia, the spleen and liver become moderately enlarged Roentgenographic changes occur in the skull and other bones The earliest change in the skull is a "ground glass" appearance and a peculiar radial striation ("hair on end") is seen Neurologic manifestations due to thrombosis are common, they include hemiplegia, aphasia headache convulsions, meningeal symptoms cranial nerve palsies, and paresthesia of the extremities

*Laboratory Findings* —Commonly, a red-blood cell count varying between 1,000 000 and 2 000,000 per c mm is found and with

Fig 187 —Above blood in sickle cell anemia photomicrograph of blood of patient with sickle cell anemia Note the oat and sickle-shaped cells and numerous cells with an elevation in the center Below photomicrograph of blood of same patient after standing several hours under sealed cover glass (Haden courtesy of Arch Int Med)

this there is a corresponding reduction in the hemoglobin hence the color index is normal The anemia is most frequently of the normocytic variety but it may be either macrocytic or microcytic The characteristic findings are the sickle cells These may be seen on a stained smear but are observed to best advantage on a sealed wet-film preparation that has stood for six or more hours Nucleated red cells are usually numerous and the reticulocytes as a rule, average between 5 and 25 per cent The blood bilirubin is frequently increased to from 1 to 3 mg per 100 cc of blood the icterus index varies between 15 to 25 units There is commonly a leukocytosis of from 12 000 to 30 000 per c mm and the platelets are moderately increased

*Treatment and Prognosis* —No specific remedy for sickle cell anemia is known but blood transfusions may induce a remission that lasts for several months but severe reactions may follow the transfusions Liver, ventriculin and iron are ineffective against the anemia The only therapy indicated is general hygienic measures treatment of cardiac failure if present by the usual measures and local treatment of the leg ulcers There is no convincing evidence that splenectomy is beneficial although this has been tried in a few cases The patients are often underdeveloped and emaciated Exacerbations of the disease may be prolonged and frequent and seriously handicap the patient On the other hand, there may be long latent periods during which the patient suffers but slight inconvenience from the disease In general however sickle cell anemia must be regarded as a serious condition which may ultimately result in death although it is not incompatible with survival to an advanced age The sickle cell trait is symptomless and is of no importance to the individual except insofar as it may be transmitted to his offspring

## MEDITERRANEAN ANEMIA

*Synonyms* —Cooley s anemia thallassemia erythroblastic anemia

*Definition* —Mediterranean anemia is a chronic microcytic hypochromic anemia It is often familial probably always hereditary, and limited largely to those of Greek Italian and Sicilian parentage It is characterized by many immature red cells in the peripheral blood, erythroid hyperplasia of the bone marrow flattened erythrocytes with many target cells showing decreased hypotonic fragility and typical x ray changes in the bones

*Etiology* —It seems evident that Mediterranean anemia stems from an inherited defect in the red cell which makes it more susceptible to hemolysis hence the laboratory findings reflect expressions of this defect *plus those of a hemolytic anemia* The defective red cells live only a short time Hemolysis is excessive, as shown by the anemia and increased icterus index The bone marrow as in other hemolytic anemias attempts to compensate for the increased cell loss hence there is erythroid hyperplasia with the appearance of an increased number of reticulocytes and nucleated cells in the peripheral blood

At autopsy abundant depositions of iron are found in the tissues The spleen is usually very large with infarcts and adhesions The bone marrow is hyperplastic There is a proliferation of new bone with a thickening of the calvarium that results in the radial arrangement of bone spicules which gives the so-called hair-on-end' radiograph

*Symptoms and Signs* —The onset of the disease is gradual but the anemia usually

portion of the patients there is definite cardiac hypertrophy not infrequently, there are symptoms of chronic cardiac failure A history of recurrent attacks of painful joints in a young person with an enlarged heart and an apical systolic murmur sometimes leads to an incorrect diagnosis of rheumatic mitral insufficiency Early in sickle cell anemia, the spleen and liver become moderately enlarged Roentgenographic changes occur in the skull and other bones The earliest change in the skull is a "ground glass" appearance and a peculiar radial striation ("hair on end") is seen Neurologic manifestations due to thrombosis are common they include hemiplegia, aphasia, headache convulsions, meningeal symptoms, cranial nerve palsies, and paresthesia of the extremities

*Laboratory Findings* —Commonly, a red blood cell count varying between 1 000,000 and 2 000 000 per c mm is found and, with

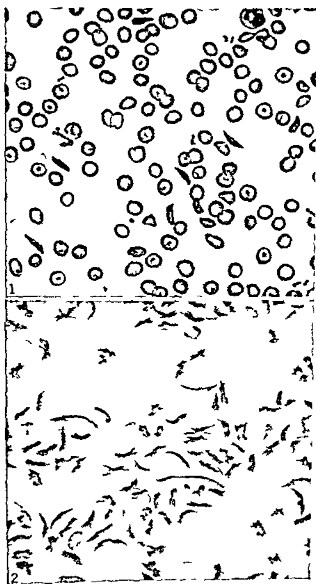

Fig 187 —Above blood in sickle cell anemia photomicrograph of blood of patient with sickle cell anemia Note the oat- and sickle-shaped cells and numerous cells with an elevation in the center Below photomicrograph of blood of same patient after standing several hours under sealed cover glass (Haden courtesy of Arch Int Med )

first child affected the symptoms may be mild. These usually become more severe in the children of succeeding pregnancies. As the symptoms are accelerated, intra-uterine death often occurs.

*Blood.*—The anemia is macrocytic and usually severe, the red cell count being in the neighborhood of one million. Large numbers of nucleated red cells are present. There is usually leukocytosis. The nucleated erythrocytes are of all types, but with survival of the child these disappear in a few days.

*Treatment.*—If not dead at birth, the child is likely to die within a week. Supportive measures should be instituted at once. Blood transfusions from an Rh negative donor—and preferably from one that is also a group-O donor—should be given intravenously. If a mother has previously given birth to a child with erythroblastosis she will usually exhibit a rising anti-Rh titer late in her current pregnancy. If this is found, it is best to induce labor to forestall the continuing hemolysis. Exsanguination of the newborn child and replacement with Rh negative group-O blood may be necessary.

## ANEMIA IN PREGNANCY

By Frank H. Bethell, M.D.

Anemia is a common accompaniment of pregnancy and is usually due to preexisting deficiency of substances required for normal red cell production and hemoglobin synthesis. However, the lowering of erythrocyte values which occurs almost uniformly during gestation does not necessarily constitute anemia. It is accounted for by increased plasma volume and is therefore a state of hydremia rather than true anemia.

The significance of anemia in pregnancy gains weight from the fact that the fetal requirements for blood formation must be supplied by the mother. Although a great many substances are utilized in the formation of blood cells, the deficiencies most likely to occur are of iron, protein and certain fractions of the vitamin B complex. The immediate needs of the fetus in the manufacture of red blood cells are adequately met even when there is a severe deficiency in the mother, although this entails still further depletion of her own materials. On the other hand, the reserves normally stored for use in the first months of extra-uterine life are supplied scarcely if at all in the presence of such deficiency. This division of scanty essential materials between mother and fetus has been shown to be true in the case of iron, and it probably also holds for other constituents of the blood cells.

Anemia in pregnancy may be entirely coincidental, as illustrated by persons with various disorders affecting the blood or blood forming organs. But in such cases the added demands of pregnancy materially increase the disability caused by the original condition. Thus women suffering from leukemia, aplastic anemia, untreated pernicious anemia or certain hemolytic anemias tolerate gestation poorly and frequently fail to secure a viable child.

In the great majority of cases of anemia occurring during pregnancy, the condition is attributable to the gravid state. Yet the preexisting health of the pregnant woman, and especially her nutritional status with respect to the substances mentioned above, largely determine whether or not the added demands of gestation will result in anemia.

Before the incidence of anemia in pregnancy can be discussed, a normal range of values must be defined. It is the lack of universally accepted standards of normality which has made difficult or impossible a comparison of the data supplied in many reported series of cases. Standards based on the examination of subjects assumed to be healthy because free from apparent disease are too low when compared with values obtained for persons who meet rigid physical and nutritional requirements. Quantitatively the difference is not great, but anemia of slight degree should be regarded less as a cause of disability than as an indication of suboptimum health, often dependent upon nutritional inadequacy. Erythrocyte and hemoglobin values reach their lowest points during the sixth or seventh month of gestation. Red blood cell counts of less than 3,700,000 per cu. mm. and hemoglobin values below 11 grams per 100 cc. observed at any time during pregnancy

appears during the first two years of life The first symptoms are pallor and enlarged spleen The disease progresses slowly the anemia increases, the spleen grows larger, and growth is retarded A mongoloid cast of countenance is frequently found among the victims of the condition As the disease continues the spleen often becomes immense and the anemia extreme and there is usually some enlargement of the liver

The typical roentgenographic signs are not always present but are striking when they are when these signs are well established there is a diploic space with vertical striations at right angles to the inner tables

*Blood* —Early in the disease there are few distinctive features and only a mild anemia The typical large number of normoblasts appears later The anemia is microcytic and hypochromic The red cell count is usually between 2 and 3 millions per cubic millimeter and the hemoglobin measures between 20 and 30 per cent The reticulocytes are increased (5 10 per cent) and, with progression there are diffuse basophilia poikilocytosis, and anisocytosis Macrocytes are common although the mean cell volume is small A target cell shows a deeply stained center a clear area and a deeply stained periphery The macrocytes often show irregularly distributed hemoglobin 'Target cells are looked on as characteristic of Mediterranean anemia but are also seen in other conditions such as sickle cell anemia and obstructive jaundice

The presence of nucleated red blood cells as typical and immature normoblasts and microblasts is characteristic of advanced disease

The leukocytes are usually increased in number, varying between 10 000 and 25 000 per cubic millimeter Immature white cells may appear

The red cells show decreased hypotonic fragility, as one would expect since the cell thickness is decreased

The icterus index is typically elevated

*Treatment* —The treatment of Cooley s anemia is purely symptomatic since the hereditary defect is not influenced It differs from other forms of microcytic anemia in that it does not respond to iron therapy Liver and drugs produce no effect Blood transfusion is palliative only

*Prognosis and Course* —If the disease occurs early in the patient s life, it gradually progresses to death Survival to adulthood is rare but is more common than previously thought It is recognized, however, that mild cases do exist In these the progress of the disease is so slow that it may not be recognized till the victim is an adult A carrier state in adults is also recognized

## ERYTHROBLASTOSIS FETALIS

*Synonyms* —Erythroblastosis neonatorum hydrops fetalis congenital anemia of the newborn icterus gravis

*Definition* —Three serious diseases of the newborn, icterus gravis congenital anemia of the newborn and hydrops fetalis are included in the general term *erythroblastosis fetalis* This erythroblastosis is characterized by excessive hemolysis and abnormal erythropoiesis

The three diseases have three conditions in common anemia with many erythroblasts enlargement of both spleen and liver and extra medullary formation of blood cells

*Etiology* —The disease is primarily an abnormal hemolysis due to isoimmunization of an Rh negative mother by an Rh positive fetus Immune bodies in the blood of the mother increase in intensity with each Rh-positive child hence manifestation of the condition becomes more severe in each child The early evidence of the condition is anemia with more prolonged and intense immunization fetal hydrops develops

*Pathology* —Intense yellow-staining of all the body tissues and enlargement of both liver and spleen are the principal pathological features of the disease The bone marrow shows active hematopoiesis Extramedullary hematopoiesis is striking

*Symptoms and Signs* —The classic symptoms of the disease are jaundice soon after birth with a rapid development of anemia In infants most severely affected edema also develops early There is a great variation in the combination of jaundice anemia, and hydrops The blood shows many nucleated erythrocytes With a mother s

first child affected the symptoms may be mild These usually become more severe in the children of succeeding pregnancies As the symptoms are accelerated intrauterine death often occurs

*Blood* — The anemia is macrocytic and usually severe, the red-cell count being in the neighborhood of one million Large numbers of nucleated red cells are present There is usually leukocytosis The nucleated erythrocytes are of all types but with survival of the child these disappear in a few days

*Treatment* —If not dead at birth the child is likely to die within a week Supportive measures should be instituted at once Blood transfusions from an Rh negative donor—and preferably from one that is also a group-O donor—should be given intravenously If a mother has previously given birth to a child with erythroblastosis she will usually exhibit a rising anti Rh titer late in her current pregnancy If this is found it is best to induce labor to forestall the continuing hemolysis Exsanguination of the newborn child and replacement with Rh negative group-O blood may be necessary

## ANEMIA IN PREGNANCY

By Frank H Bethell M D

Anemia is a common accompaniment of pregnancy and is usually due to preexisting deficiency of substances required for normal red-cell production and hemoglobin synthesis However the lowering of erythrocyte values which occurs almost uniformly during gestation does not necessarily constitute anemia It is accounted for by increased plasma volume and is therefore a state of hydremia rather than true anemia

The significance of anemia in pregnancy gains weight from the fact that the fetal requirements for blood formation must be supplied by the mother Although a great many substances are utilized in the formation of blood cells the deficiencies most likely to occur are of iron protein and certain fractions of the vitamin B complex The immediate needs of the fetus in the manufacture of red blood cells are adequately met even when there is a severe deficiency in the mother although this entails still further depletion of her own materials On the other hand the reserves normally stored for use in the first months of extra uterine life are supplied scarcely if at all in the presence of such deficiency This division of scanty essential materials between mother and fetus has been shown to be true in the case of iron and it probably also holds for other constituents of the blood cells

Anemia in pregnancy may be entirely coincidental as illustrated by persons with various disorders affecting the blood or blood forming organs But in such cases the added demands of pregnancy materially increase the disability caused by the original condition Thus women suffering from leukemia aplastic anemia untreated pernicious anemia or certain hemolytic anemias tolerate gestation poorly and frequently fail to secure a viable child

In the great majority of cases of anemia occurring during pregnancy the condition is attributable to the gravid state Yet the preexisting health of the pregnant woman and especially her nutritional status with respect to the substances mentioned above largely determine whether or not the added demands of gestation will result in anemia

Before the incidence of anemia in pregnancy can be discussed a normal range of values must be defined It is the lack of universally accepted standards of normality which has made difficult or impossible a comparison of the data supplied in many reported series of cases Standards based on the examination of subjects assumed to be healthy because free from apparent disease are too low when compared with values obtained for persons who meet rigid physical and nutritional requirements Quantitatively the difference is not great but anemia of slight degree should be regarded less as a cause of disability than as an indication of suboptimum health often dependent upon nutritional inadequacy Erythrocyte and hemoglobin values reach their lowest points during the sixth or seventh month of gestation Red blood cell counts of less than 3 700 000 per cu mm and hemoglobin values below 11 grams per 100 cc observed at any time during pregnancy

should be regarded as probably abnormal although hydremia may, in some instances account for values as low as 3 500,000 red cells and 10 grams of hemoglobin

Among the many causes of anemia affecting both *gravid* and *nongravid* women, specific deficiencies may be regarded as among the most important Their significance is based upon their frequency and their vulnerability to the three chief weapons of disease control prevention, recognition, and correction Since particular deficiencies result in characteristic abnormalities in the blood picture, exact diagnosis and effective treatment require careful hematologic evaluation with particular emphasis upon the size of the red blood cells and the degree to which they are filled with hemoglobin In some cases, bone marrow examination is of great aid in the interpretation of the hemopoietic disturbance and as a guide to therapy

Iron Deficiency Anemia of Pregnancy —Depending upon the nature of the group under observation iron-deficiency anemia occurs in from 15 to 30 per cent of gravid women Fetal requirement for iron is greatest during the last trimester of gestation yet hypochromic anemia if it occurs, *usually manifests itself by the fifth month* of pregnancy *Such anemia is dependent upon iron depletion before the onset of pregnancy,* due most often to low dietary iron intake menstrual abnormalities or previous pregnancies The blood picture characteristic of iron deficiency in pregnancy is hypochromic with a low color index Microcytosis is less conspicuous than in similar anemias occurring in nongravid women

Careful dietary studies have shown that the incidence of hypochromic anemia is extremely low *among pregnant women who* habitually get a diet supplying 16 or more mgm of iron daily The incidence is greatest among those *who received* less than 8 mgm of food iron When iron depletion with anemia is present, correction of the diet will not suffice to restore normal blood values and reliance must be placed on medicinal iron preparations Gastrointestinal intolerance to the more readily ionizable ferrous salts occurs quite *frequently in pregnant* women It can usually be prevented by having the medication taken immediately after meals and by starting with a single daily dose of 0 3 gm of ferrous sulfate and subsequently adding doses until one is taken after each meal Ferrous gluconate is sometimes better tolerated than the sulfate, and there is a colloidal preparation of iron available in capsules (Ferrocol) which is especially well received

Macrocytic Anemia of Pregnancy — It has been common experience that a considerable number of cases of anemia associated with pregnancy fail to respond satisfactorily to iron therapy alone *Evidence has been produced that such anemia* is dependent upon other deficiencies of the diet and that it may be differentiated from simple iron deficiency by a tendency of the circulating red cells to exhibit significant macrocytosis The incidence of macrocytic anemia in pregnancy usually of mild degree has been found in different groups of subjects, to vary between 10 and 20 per cent Dietary studies have revealed a close correlation between the occurrence of such anemia and low intake of protein, especially that derived from animal sources Improvement of the *diet with daily intake of 100 gms or more* of protein of good quality has led to correction of the anemia even if treatment was deferred until the last trimester of gestation

It seems probable that the so-called "pernicious anemia of pregnancy a rare entity represents a more severe and progressive stage of the relatively common milder form of macrocytic anemia Such anemia may respond to a high intake of protein *alone Response to parenteral administration* of refined and concentrated liver extracts is poor and vitamin $B_1$ has been shown to be completely ineffective in the treatment of pernicious anemia of pregnancy *and the puerperium Folic acid on the* other hand produces excellent responses in patients with this disorder Crude parenteral liver extracts in large doses as well as oral preparations of liver are also effective in *the treatment of pernicious* anemia of pregnancy and the puerperium

In summary anemia is frequently associated with pregnancy and is usually due to

long-standing suboptimal nutrition with menstrual abnormalities and previous pregnancies serving as important aggravating factors Correction of anemia in pregnancy requires recognition of the nature of the deficiency which is facilitated by study of the morphologic changes of the circulating red cells and sometimes by bone marrow examination The important therapeutic agents in the management of such anemia are high dietary intake of good quality protein medicinal iron preparations and when severe macrocytic anemia is present folic acid

Day L A Hall B E and Pease C L Macrocytic Anemia of Pregnancy Refractory to Vitamin $B_1$ Therapy Response to Treatment with Folic Acid. Proc Staff Meet Mayo Clin 1949 *24* 149

## SIMPLE CHRONIC ANEMIA

By simple chronic anemia is meant normocytic normochromic anemia associated with a wide variety of pathologic conditions These include some cases of chronic infection malignancy nutritional deficiency states endocrine disorders (such as hypothyroidism and Addison s disease) and metabolic disturbances (such as chronic hepatic disease and chronic nephritis with uremia)

The blood picture in simple chronic anemia is nonspecific and treatment except for blood transfusions is dependent upon diagnosis and correction of the primary condition The lowered erythrocytic values are probably due in most instances to a decreased rate of production of red corpuscles and hemoglobin Such anemia should be carefully distinguished from hemolytic myelophthisic and specific nutritional deficiency anemias

## POLYCYTHEMIA

By Russell L Haden M D

*Synonyms* —Erythremia polycythemia rubra vera Vaquez s disease Osler s disease

*Definition* —Polycythemia is an abnormal increase in red blood cells in the circulating blood Since a cell count indicates only the number of cells per unit volume of blood a high count may be due to blood concentration from dehydration Here the increase is only apparent since the total number of cells is unchanged In true polycythemia or erythremia there is an abnormally large mass of red cells per kilogram of body weight This is due to an increase in total blood volume as well as to a greater number of cells per unit volume of blood Erythrocytosis indicates an increased number of red cells without an increase in red-cell mass per kilogram Few men have a red-cell count above 5 500 000 and any count above 6 000 000 is usually abnormal The comparable figures for women are 5 000 000 and 5 500 000 An erythrocytosis is not uncommon in obese plethoric men and women and may also result from the conditions listed below as causative factors in erythremia

Polycythemia vera or erythremia may be due to some chronic interference with oxygenation an interference due (1) to low barometric pressure in high altitudes (2) to a disturbance in pulmonary circulation (as in Ayerza s disease) (3) to a by passing of the lungs in congenital heart disease or (4) to an alteration in blood pigment (as in methemoglobinemia) In all such cases the hemoglobin cannot properly fulfill its function of carrying oxygen so the total amount may be increased to compensate for the decreased oxygen capacity This condition is designated symptomatic or secondary polycythemia vera since there is an evident cause of the increase in red-cell mass per kilogram of body weight Idiopathic polycythemia vera occurs with known cause A classification of polycythemia is summarized in table 61

*Etiology* —Since anoxemia is a known stimulus for red-cell overproduction and is the evident cause of the high red-cell counts found in cases of symptomatic polycythemia vera attempts have been made to explain the idiopathic type on this basis but no such explanation has been proved No disturbance in the gas-exchanging functions

should be regarded as probably abnormal, although hydremia may, in some instances account for values as low as 3 500 000 red cells and 10 grams of hemoglobin

Among the many causes of anemia affecting both gravid and nongravid women, specific deficiencies may be regarded as among the most important Their significance is based upon their frequency and their vulnerability to the three chief weapons of disease control prevention, recognition and correction Since particular deficiencies result in characteristic abnormalities in the blood picture, exact diagnosis and effective treatment require careful hematologic evaluation with particular emphasis upon the size of the red blood cells and the degree to which they are filled with hemoglobin In some cases, bone marrow examination is of great aid in the interpretation of the hemopoietic disturbance and as a guide to therapy

IRON DEFICIENCY ANEMIA OF PREGNANCY —Depending upon the nature of the group under observation iron-deficiency anemia occurs in from 15 to 30 per cent of gravid women Fetal requirement for iron is greatest during the last trimester of gestation yet hypochromic anemia if it occurs usually manifests itself by the fifth month of pregnancy *Such anemia is dependent upon iron depletion before the onset of pregnancy,* due most often to low dietary iron intake, menstrual abnormalities or previous pregnancies The blood picture characteristic of iron deficiency in pregnancy is hypochromic with a low color index Microcytosis is less conspicuous than in similar anemias occurring in nongravid women

Careful dietary studies have shown that the incidence of hypochromic anemia is extremely low among pregnant women who habitually get a diet supplying 16 or more mgm of iron daily The incidence is greatest among those who received less than 8 mgm of food iron When iron depletion with anemia is present, correction of the diet will not suffice to restore normal blood values and reliance must be placed on medicinal iron preparations Gastrointestinal intolerance to the more readily ionizable ferrous salts occurs quite frequently in pregnant women It can usually be prevented by having the medication taken immediately after meals and by starting with a single daily dose of 0 3 gm of ferrous sulfate and subsequently adding doses until one is taken after each meal Ferrous gluconate is sometimes better tolerated than the sulfate, and there is a colloidal preparation of iron available in capsules (Ferrocol) which is especially well received

MACROCYTIC ANEMIA OF PREGNANCY — It has been common experience that a considerable number of cases of anemia associated with pregnancy fail to respond satisfactorily to iron therapy alone Evidence has been produced that such anemia is dependent upon other deficiencies of the diet and that it may be differentiated from simple iron deficiency by a tendency of the circulating red cells to exhibit significant macrocytosis The incidence of macrocytic anemia in pregnancy usually of mild degree, has been found in different groups of subjects to vary between 10 and 20 per cent Dietary studies have revealed a close correlation between the occurrence of such anemia and low intake of protein especially that derived from animal sources Improvement of the diet with daily intake of 100 gms or more of protein of good quality has led to correction of the anemia even if treatment was deferred until the last trimester of gestation

It seems probable that the so-called pernicious anemia of pregnancy a rare entity represents a more severe and progressive stage of the relatively common milder form of macrocytic anemia Such anemia may respond to a high intake of protein alone Response to parenteral administration of refined and concentrated liver extracts is poor and vitamin $B_1$ has been shown to be completely ineffective in the treatment of pernicious anemia of pregnancy and the puerperium Folic acid on the other hand produces excellent responses in patients with this disorder Crude parenteral liver extracts in large doses as well as oral preparations of liver are also effective in the treatment of pernicious anemia of pregnancy and the puerperium

In summary anemia is frequently associated with pregnancy and is usually due to

those obtained with radioactive phosphorus

Nitrogen mustard also gives excellent results in producing remission. The drug is given as for Hodgkin's disease in a course of 0.1 milligram per kilogram of body weight on four consecutive days, but a total dosage over the four-day period should not exceed 24 milligrams.

TABLE 61.—CLASSIFICATION OF POLYCYTHEMIA

1 Erythrocytosis (secondary or simple polycythemia)
   Increase in number of erythrocytes without increase in red-cell mass per kilogram
2 Polycythemia vera or erythremia
   Increase in number of erythrocytes with increase in red-cell mass per kilogram
   A Symptomatic polycythemia vera caused by
      (1) low barometric pressure
      (2) a impaired oxygenation due to congenital heart disease or arterio-venous fistula in lung or
         b decreased aerating surface due to lung disease
      (3) impaired capacity of hemoglobin to carry oxygen as in methemoglobinemia
   B Idiopathic polycythemia vera of unknown cause

## HEMORRHAGIC DISEASES

By EUGENE L. LOZNER, M.D.

*Definition.*—A hemorrhagic disease may be said to exist whenever a patient shows a tendency to bleed excessively. Such bleeding may occur into or from the skin, into or from the mucous membrane, into a joint space or, in fact, into any part of the body, without any known trauma or with trauma so trivial that the normal individual would have shown little or no evidence of bleeding. In most patients with hemorrhagic disease bleeding occurs at several sites in the body, and there is little doubt that a generalized breakdown in the hemostatic mechanism has taken place. In other patients the bleeding from one source may be particularly prominent, for example, that from the uterine mucosa or that into one joint space. Such patients may be treated by gynecologists or orthopedic surgeons before it is appreciated that the local bleeding is merely a manifestation of a more generalized disorder.

*Pathophysiology and Classification.*—In order to understand satisfactorily the nature of the hemorrhagic diseases it is necessary to appreciate the nature of the normal hemostatic mechanisms. Unfortunately there still remains considerable dispute about the latter. In brief, the body possesses two main defenses against hemorrhage. For want of better terms these may be called the *vascular defense* and the *blood-coagulability defense*. Whenever either of these fails the possibility of hemorrhage exists. Failure of these defenses may occur either because the trauma has overwhelmed them or because they are unequal to even a trivial trauma. It is the latter situation which is most often observed in the hemorrhagic diseases. The vascular defense consists in (1) the ability of blood vessels to maintain their integrity despite increases in intravascular pressure and despite trauma, (2) *their faculty of constriction and retraction* when severed, and (3) the mobilization of platelets to the vascular wound where they agglutinate and cause the retraction of fibrin. The blood-coagulability defense consists in the ability of the blood to clot upon being shed or, expressed in another way, the transformation of fibrinogen catalyzed by *the enzyme thrombin from its soluble* state within the blood vessels to its insoluble state, or gel form (known as fibrin), upon the release of blood from the blood vessels. In the conversion of fibrinogen to fibrin by thrombin at least three other constituents of the plasma play a role: ionized calcium, prothrombin and thromboplastin. The source of the latter material remains controversial. It is defined fundamentally as a physiological complex which catalyzes the conversion of prothrombin to thrombin in the presence of ionized calcium. Thromboplastic activity has been found in many tissues and exists in the plasma itself. It is found in high concentrations in such tissues as lung or brain. Thromboplastin or something very closely allied to it may be present in the platelets. Recent studies have indicated that, in addition to the above-mentioned three constituents of the plasma, other accelerator substances may play a role in the conversion of prothrombin to thrombin. These accelerator substances are present in both plasma and serum. The

of the blood such as occurs in methemoglobinemia, has ever been demonstrated. The possibility of a defect in oxygenation, a defect due to some abnormality in the pulmonary epithelium, has also been suggested but not demonstrated. There is nothing to suggest that the cells live longer than normal. The bone marrow studies show overproduction of red cells.

*Reznikoff, Foot, and Bethea* have emphasized changes in the arteries of the marrow in idiopathic polycythemia vera similar to those seen in thromboangiitis obliterans. Most observers agree that the bone marrow is primarily at fault in the idiopathic type. The characteristic erythroblastic characteristic of polycythemia vera may be analogous to the myeloblastic overactivity seen in chronic myeloid leukemia.

*Pathology.*—With the characteristic increase in blood volume due to the greater number of red blood cells, the veins are distended and the organs engorged. *Varices are common; thromboses are frequent.*

The spleen is enlarged in all advanced cases, but the diagnosis often may be made before splenomegaly occurs. There is hyperplasia of the pulp, mostly with mature red blood cells. The bone marrow is red and shows hyperplasia of all the marrow elements.

*Symptoms and Signs.*—Early in the disease there are few symptoms. The most important are headache, tiredness and vertigo. Cyanosis and splenomegaly are present in most advanced cases. Early in the disease there may be only ruddiness of complexion and the spleen may or may not be enlarged. As the disease progresses real cyanosis develops. But there may be full blown polycythemia vera without changes in the skin.

Vascular complications are common. Venous and arterial thromboses are frequent. These may occur at widely varying locations. Venous varicosities are seen in many patients. Hypertension also frequently occurs. This may not necessarily be due to the disease since most victims of polycythemia vera are middle-aged or older. Many patients develop gout when the disease is well marked. Erythromelalgia may be observed.

*Blood.*—The red cell count, the hematocrit reading, and the hemoglobin determination are always increased in polycythemia. The red cells usually number more than six million. The hematocrit reading is seldom less than 55 cc. per 100 cc. of blood. Red cell counts as high as 10,000,000 may occur. The blood volume is always increased in polycythemia vera; this is due to the increase in red-cell mass. The change in the red cell mass is best indicated by the number of *cubic centimeters of packed red cells per kilogram of body weight*; this number is determined from the blood volume and the hematocrit reading. In the absence of dehydration, *a red cell count of six million or more* with a hematocrit reading of 55 or more is presumptive evidence of polycythemia vera.

Leukocytosis is common and may occur very early in the course of the disease. Later very high counts may be observed. When *the spleen becomes very large and the white* cell count very high, immature white cells, myelocytes and myeloblasts are common. The blood at this stage may suggest myeloid leukemia.

The platelet count may be high and be a factor in thrombosis, especially when the *viscosity of the blood is high.*

*Treatment.*—It is questionable whether symptomatic polycythemia vera should be treated unless the *increase in red cells is so* extreme as to interfere with the circulation. In idiopathic polycythemia vera this does cause embarrassment of the circulation and as it is progressive, treatment should be given. Various hemolytic agents such as phenylhydrazine have been tried but simply produce a hemolytic anemia. The excess of blood may be removed by frequent venesection with the production of an iron deficiency (microcytic) anemia. But it is far better to prevent excessive formation of red cells in the bone marrow. $P_{32}$ gives excellent results but is not generally available. Radioactive phosphorus is given by mouth or by vein in varying amounts and at varying intervals. The action is slow. Similarly, *x*-ray irradiation may be used but the results are less satisfactory than

those obtained with radioactive phosphorus

Nitrogen mustard also gives excellent results in producing remission. The drug is given as for Hodgkin's disease in a course of 0.1 milligram per kilogram of body weight on four consecutive days but a total dosage over the four day period should not exceed 24 milligrams.

TABLE 61.—CLASSIFICATION OF POLYCYTHEMIA

1 Erythrocytosis (secondary or simple polycythemia)
   Increase in number of erythrocytes without increase in red cell mass per kilogram
2 Polycythemia vera or erythremia
   Increase in number of erythrocytes with increase in red cell mass per kilogram
   A Symptomatic polycythemia vera caused by
      (1) low barometric pressure
      (2) a impaired oxygenation due to congenital heart disease or arterio-venus fistula in lung or
          b decreased aerating surface due to lung disease
      (3) impaired capacity of hemoglobin to carry oxygen as in methemoglobinemia
   B Idiopathic polycythemia vera of unknown cause

## HEMORRHAGIC DISEASES

By EUGENE L LOZNER M D

*Definition.*—A hemorrhagic disease may be said to exist whenever a patient shows a tendency to bleed excessively. Such bleeding may occur into or from the skin into or from the mucous membrane into a joint space or in fact into any part of the body without any known trauma or with trauma so trivial that the normal individual would have shown little or no evidence of bleeding. In most patients with hemorrhagic disease bleeding occurs at several sites in the body and there is little doubt that a generalized breakdown in the hemostatic mechanism has taken place. In other patients the bleeding from one source may be particularly prominent for example that from the uterine mucosa or that into one joint space. Such patients may be treated by gynecologists or orthopedic surgeons before it is appreciated that the local bleeding is merely a manifestation of a more generalized disorder.

*Pathophysiology and Classification.*—In order to understand satisfactorily the nature of the hemorrhagic diseases it is necessary to appreciate the nature of the normal hemostatic mechanisms. Unfortunately there still remains considerable dispute about the latter. In brief the body possesses two main defenses against hemorrhage. For want of better terms these may be called the *vascular defense* and the *blood-coagulability defense*. Whenever either of these fails the possibility of hemorrhage exists. Failure of these defenses may occur either because the trauma has overwhelmed them or because they are unequal to even a trivial trauma. It is the latter situation which is most often observed in the hemorrhagic diseases. The vascular defense consists in (1) the ability of blood vessels to maintain their integrity despite increases in intravascular pressure and despite trauma (2) their faculty of constriction and retraction when severed and (3) the mobilization of platelets to the vascular wound where they agglutinate and cause the retraction of fibrin. The blood-coagulability defense consists in the ability of the blood to clot upon being shed or expressed in another way the transformation of fibrinogen catalyzed by the enzyme thrombin from its soluble state within the blood vessels to its insoluble state or gel form (known as fibrin) upon the release of blood from the blood vessels. In the conversion of fibrinogen to fibrin by thrombin at least three other constituents of the plasma play a role ionized calcium prothrombin and thromboplastin. The source of the latter material remains controversial. It is defined fundamentally as a physiological complex which catalyzes the conversion of prothrombin to thrombin in the presence of ionized calcium. Thromboplastic activity has been found in many tissues and exists in the plasma itself. It is found in high concentrations in such tissues as lung or brain. Thromboplastin or something very closely allied to it may be present in the platelets. Recent studies have indicated that in addition to the above mentioned three constituents of the plasma other accelerator substances may play a role in the conversion of prothrombin to thrombin. These accelerator substances are present in both plasma and serum. The

material in serum is much the more potent of the two

The exact role of the platelets in blood coagulation and in vascular defense remains poorly understood It is generally agreed that the platelets are important in the retraction of fibrin, once it is formed, and in the general structure of the thrombus which seals a blood vessel It is also agreed that a diminution of platelets is frequently associated with an increase in capillary fragility and an increased tendency to bleed from small wounds Thus there appears to be a positive correlation between platelets and vascular function For this reason, the hemorrhagic diseases in which platelets are reduced may be included in those in which vascular defense has failed

The hemorrhagic diseases may be classified into two groups—those in which vascular defense has failed and those in which blood coagulability defense has failed (Table 61) In the former group there may be a still further subclassification depending upon whether the platelet count is normal or reduced If normal, the term nonthrombocytopenic purpura may be applied When the platelets are reduced the term thrombocytopenic purpura is used

## THROMBOCYTOPENIC PURPURA

*Synonyms* —Werlhof s disease (*see classification below*) purpura hemorrhagica morbus maculosus hemorrhagicus

*Definition* —Thrombocytopenic purpura is a hemorrhagic disease characterized by bleeding into and from the skin and mucous membranes diminished platelets increased capillary fragility, prolonged bleeding time, poor clot retraction and decreased prothrombin consumption

*Etiology and Classification* —There are essentially three types of thrombocytopenic purpura—the idiopathic variety etiology unknown (Werlhof s disease primary thrombocytopenic purpura essential thrombocytopenic purpura) the toxic or allergic variety, in which a drug or antigen can definitely be implicated and the secondary (symptomatic) variety in which the thrombocytopenia is but one manifestation of either a generalized disorder of the bone marrow, (such as leukemia aplastic anemia, pernicious anemia, lymphomatosis, carcinomatosis, or tuberculosis) or a generalized disorder of the spleen producing the syndrome of "hypersplenism (such as Lænnec s cirrhosis, congestive splenomegaly, or Gaucher's disease) Of these varieties, the idiopathic one is probably the least common and secondary thrombocytopenia the most common

## IDIOPATHIC THROMBOCYTOPENIC PURPURA

This disease is most commonly seen in children in whom the incidence as to sex is equal and there is a tendency to spontaneous remission In adults, the incidence ratio females to males, is at least 3 1, suggesting to some an endocrine aspect to the condition

*Pathology and Physiology* —At present, there are two major schools of thought on the pathogenesis of idiopathic thrombocytopenia The first was probably introduced by Frank (1915), who suggested that the spleen inhibited the formation of platelets from the megakaryocytes in the bone marrow The second was suggested by Kaznelson a year later who likening the situation to congenital hemolytic jaundice, postulated that the spleen actually destroyed the platelets and so produced thrombocytopenia The first school is supported to some extent, by the occasional observation that extracts of the spleens of patients with this type of purpura will produce thrombocytopenia when injected into animals The recent studies in congenital thrombocytopenic purpura suggest the placental transfer of a humoral substance, inasmuch as it has been observed that mothers with thrombocytopenic purpura, whether splenectomized or not, usually give birth to babies with transient thrombocytopenia

The findings at autopsy are chiefly those of extensive hemorrhage throughout the body The bone marrow in the usual patient shows the megakaryocytes present in normal or increased numbers Recent studies have indicated that there may also be qualitative changes in the morphology of the megakaryocytes such as the absence of platelet formation The bone marrow may

also be hyperplastic particularly in the erythroid series as the result of acute and chronic blood loss It is of significance in this disorder that the size of the spleen is almost always within normal limits This is in contrast to other cytopenic disorders in which splenomegaly usually prevails

*Symptoms* —The disease varies in both severity and course There may be an acute, rather fulminating course with extensive bleeding from the skin and mucous membranes and with menorrhagia to the point of producing severe anemia and peripheral vascular collapse On the other hand some patients have only mild bruising of the skin moderate purpura and relatively little bleeding from the mucous membranes In the fulminating cases and also unfortunately, in some of the milder cases, cerebral vascular hemorrhage may supervene

Fig 188 —Strongly positive tourniquet test in a case of chronic purpura hemorrhagica Platelet count 40 000 per c mm bleeding time forty two minutes Note that there are few petechiæ in the area compressed by the blood pressure cuff (Wintrobe s Clinical Hematology )

*Signs* —The only signs present are those of the various hemorrhages The uterus may be palpable in instances of severe menorrhagia The spleen is rarely palpable in primary idiopathic thrombocytopenic purpura

*Course of Disease* —The course as indicated above, may vary considerably Approximately a third of the patients will have spontaneous remissions which may be more or less permanent In most of the patients there is a tendency to remission and relapse, and these are rather unpredictable In general there is a greater tendency to spontaneous remission in children and young adults than in the older age groups

*Diagnosis* —The diagnosis of idiopathic thrombocytopenic purpura rests primarily upon the laboratory findings (including those of bone marrow aspiration) and upon the exclusion of known etiologic factors such as chemical and physical agents infectious diseases allergies and the various systemic diseases which involve either the bone marrow or the spleen and may produce secondary thrombocytopenia

*Complications* —There are two complications which must be taken very seriously The first of these as already mentioned is cerebral vascular hemorrhage The second is uterine bleeding which may be excessive It is obvious that this amount of bleeding cannot go on for any length of time without serious consequences

*Laboratory Findings* —The positive findings are a reduction in the number of platelets deficiency in clot retraction a positive tourniquet test (Fig 188), and a prolonged bleeding time Important negative findings are a normal clotting time and a normal prothrombin time

Recent studies have indicated that there is a definite coagulation defect in thrombocytopenic purpura—failure of conversion of the usual amounts of prothrombin to thrombin in the course of coagulation There is sufficient conversion to result in a normal venous clotting time However when coagulation is studied more closely it is

material in serum is much the more potent of the two

The exact role of the platelets in blood coagulation and in vascular defense remains poorly understood It is generally agreed that the platelets are important in the retraction of fibrin, once it is formed, and in the general structure of the thrombus which seals a blood vessel It is also agreed that a diminution of platelets is frequently associated with an increase in capillary fragility and an increased tendency to bleed from small wounds Thus, there appears to be a positive correlation between platelets and vascular function For this reason the hemorrhagic diseases in which platelets are reduced may be included in those in which vascular defense has failed

The hemorrhagic diseases may be classified into two groups—those in which vascular defense has failed and those in which blood-coagulability defense has failed (Table 61) In the former group, there may be a still further subclassification depending upon whether the platelet count is normal or reduced If normal, the term nonthrombocytopenic purpura may be applied When the platelets are reduced, the term thrombocytopenic purpura is used

## THROMBOCYTOPENIC PURPURA

*Synonyms* —Werlhof s disease (*see classification below*), purpura hemorrhagica morbus maculosus hemorrhagicus

*Definition* —Thrombocytopenic purpura is a hemorrhagic disease characterized by bleeding into and from the skin and mucous membranes, diminished platelets increased capillary fragility, prolonged bleeding time poor clot retraction, and decreased prothrombin consumption

*Etiology and Classification* —There are essentially three types of thrombocytopenic purpura—the idiopathic variety etiology unknown (Werlhof s disease primary thrombocytopenic purpura, essential thrombocytopenic purpura), the toxic or allergic variety, in which a drug or antigen can definitely be implicated and the secondary (symptomatic) variety, in which the thrombocytopenia is but one manifestation of either a generalized disorder of the bone marrow, (such as leukemia, aplastic anemia, pernicious anemia, lymphomatosis, carcinomatosis, or tuberculosis) or a generalized disorder of the spleen producing the syndrome of "hypersplenism (such as Laennec s cirrhosis, congestive splenomegaly, or Gaucher s disease) Of these varieties, the idiopathic one is probably the least common and secondary thrombocytopenia the most common

## IDIOPATHIC THROMBOCYTOPENIC PURPURA

*This disease is most commonly seen in* children in whom the incidence as to sex is equal and there is a tendency to spontaneous remission In adults, the incidence ratio females to males, is at least 3 1, suggesting to some an endocrine aspect to the condition

*Pathology and Physiology* —At present there are two major schools of thought on the pathogenesis of idiopathic thrombocytopenia The first was probably introduced by Frank (1915), who suggested that the spleen *inhibited the formation of platelets* from the megakaryocytes in the bone marrow The second was suggested by Kaznelson a year later who likening the situation to congenital hemolytic jaundice postulated that the spleen actually destroyed the platelets and so produced thrombocytopenia The first school is supported to some extent by the occasional observation that extracts of the spleens of patients with this type of purpura will produce thrombocytopenia when injected into animals The recent studies in congenital thrombocytopenic purpura suggest the placental transfer of a humoral substance inasmuch as it has been observed that mothers with thrombocytopenic purpura, whether splenectomized or not usually give birth to babies with transient thrombocytopenia

The findings at autopsy are chiefly those of extensive hemorrhage throughout the body The bone marrow in the usual patient shows the megakaryocytes present in normal or increased numbers Recent studies have indicated that there may also be qualitative changes in the morphology of the megakaryocytes such as the absence of platelet formation The bone marrow may

should therefore be taken with regard to drug intake

2 *Physical Agents* — Thrombocytopenic purpura in this category is most commonly the result of irradiation by roentgen rays radium or the products of nuclear fission

3 *Infections* — A variety of infections associated with septicemia have been reported to be complicated by thrombocytopenia Scarlet fever diphtheria and meningococcemia are among the more common

4 *Food Sensitivity* — Thrombocytopenic purpura has been reported as being the result of sensitivity to various foods including milk citrus fruits wheat and potatoes

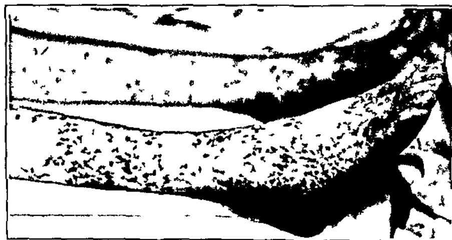

FIG 189 — Purpuric lesion in a case of scarlet fever There was no thrombocytopenia (Fox and Enzer Am Jour Med Sci)

There are some investigators who feel that most if not all cases of thrombocytopenic purpura may fall into this category Recent studies indicating the prevalence of eosinophils in the bone marrow in thrombocytopenic purpura may substantiate this theory However it is felt by most investigators that only a few cases are caused by food sensitivity

## SECONDARY (SYMPTOMATIC) THROMBOCYTOPENIC PURPURA

As indicated above thrombocytopenic purpura is often secondary to a generalized disorder of the bone marrow in which the megakaryocytes are actually mechanically displaced by other tissue This tissue may be leukemic tuberculous lymphomatous, carcinomatous, or fibrous or fatty in nature It may be erythroid tissue, as in pernicious anemia or in chronic hypochromic anemia

Thrombocytopenia may also be the result of disorders associated with enlargement of the spleen This type of thrombocytopenia is now thought to be part of the syndrome of hypersplenism in which the splenic tissue either destroys the platelets or secretes a hormone which affects maturation of the megakaryocytes or delivery of the platelets from the bone marrow Any of the splenomegalies may be associated with thrombocytopenia Among the more common ones are congestive splenomegaly Gaucher s disease Hodgkin s disease Felty s syndrome tuberculosis and sarcoid

## NONTHROMBOCYTOPENIC PURPURA

This type of purpura is characterized by a clinical syndrome milder than the thrombocytopenic variety and associated with normal platelets normal clot retraction and clotting time slight if any disturbance of bleeding time and a positive tourniquet test It may be associated with infections (Fig 189) or with drug ingestion and in some instances is associated with nutritional deficiency From the standpoint of strict

evident that there is incomplete consumption of prothrombin during the course of coagulation This seems to be due to a decrease in the amount of thromboplastin available for the conversion of prothrombin

Of considerable importance in the laboratory study of these patients is the bone marrow aspiration primarily for the purpose of excluding such conditions as leukemia pernicious anemia aplastic anemia, and lipoid reticuloendotheliosis In all these conditions, there will be diagnostic findings on bone marrow aspiration, whereas in the marrow of patients with idiopathic purpura there is little deviation from normal with the exception of a possible increase as well as morphologic changes in the megakaryocytes

Other changes in the blood are those which are the result of an acute and chronic blood loss

*Differential Diagnosis* —The differential diagnosis is primarily from other forms of thrombocytopenic purpura All the other hemorrhagic diseases are rather easily distinguished when the various laboratory tests for hemorrhagic diatheses are performed The differentiation from other forms of thrombocytopenic purpura will best be accomplished by a thorough history and physical examination bone marrow aspiration and biopsy of lymph nodes if these should be enlarged

*Treatment* —The treatment of this disorder falls into two general categories (1) expectant or conservative treatment with or without transfusions (2) splenectomy As indicated above approximately a third of the patients will have a spontaneous remission Splenectomy on the other hand will produce a remission in probably two-thirds of the cases In some of these cases splenectomy will be followed by a temporary rise in the number of platelets with a subsequent decrease in their number to below normal limits However even in this latter group there may be significant clinical improvement In other splenectomized patients there may be permanent improvement in all phases of the disease The chief reasons for delaying splenectomy in some patients are the occurrence of spontaneous remission, the fact that splenectomy is associated with a certain percentage of failures and the mortality rate connected with the operative procedure (about 5 per cent) Therefore, it would seem advisable to withhold splenectomy for two or three months in the hope of achieving a spontaneous remission In all patients when transfusions are indicated it is advisable to use blood less than 24 hours old It is felt also that the use of fresh blood definitely improves the result of splenectomy, particularly in the acute fulminating cases

A variety of other treatments have been suggested from time to time but none of these are sufficiently well documented to place them on the same basis as splenectomy or fresh blood transfusions Among these treatments are x irradiation of the spleen injection of moccasin venom, parathyroid hormone injections and ultraviolet irradiation of the body All patients should, of course receive a high protein high vitamin diet with ascorbic acid for general supportive treatment Recent preliminary studies by Bethell at Michigan and Lozner at Syracuse and Robson in Scotland indicate that adrenocorticotropic hormone and cortisone may be useful in this disorder These hormones have produced complete remissions in several patients which were sustained in some and transient in others In most patients the capillary fragility was favorably influenced during the period of administration of the hormones The exact role that these hormones will play in the treatment of this disorder is not clear, but they may be quite helpful in such situations as intractable epistaxis or menorrhagia

## TOXIC OR ALLERGIC THROMBOCYTOPENIC PURPURA

This type of purpura presents the same clinical picture as the idiopathic variety except that it is the result of known etiologic factors These factors may be enumerated as follows

1 *Drugs* —Many drugs are known to produce thrombocytopenic purpura Among these are the heavy metals—arsenic bismuth and gold Sulfonamides barbiturates and salicylates have all been reported as causing this disease A careful history

should therefore be taken with regard to drug intake

2 *Physical Agents* — Thrombocytopenic purpura in this category is most commonly the result of irradiation by roentgen rays radium or the products of nuclear fission

3 *Infections* — A variety of infections associated with septicemia have been reported to be complicated by thrombocytopenia Scarlet fever diphtheria and meningococcemia are among the more common

4 *Food Sensitivity* — Thrombocytopenic purpura has been reported as being the result of sensitivity to various foods including milk citrus fruits wheat and potatoes

displaced by other tissue This tissue may be leukemic tuberculous lymphomatous carcinomatous, or fibrous or fatty in nature It may be erythroid tissue, as in pernicious anemia or in chronic hypochromic anemia

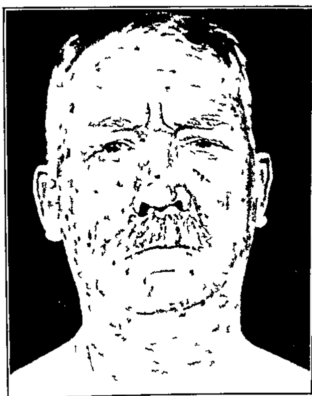
Thrombocytopenia may also be the result of disorders associated with enlargement of the spleen This type of thrombocytopenia is now thought to be part of the syndrome of "hypersplenism," in which the splenic tissue either destroys the platelets or secretes a hormone which affects maturation of the megakaryocytes or delivery of the platelets from the bone marrow Any of the splenomegalies may be associated with thrombocytopenia Among the more common ones are

FIG 189 — Purpuric lesion in a case of scarlet fever There was no thrombocytopenia (Fox and Enzer Am Jour Med Sci)

There are some investigators who feel that most if not all cases of thrombocytopenic purpura may fall into this category Recent studies indicating the prevalence of eosinophils in the bone marrow in thrombocytopenic purpura may substantiate this theory However it is felt by most investigators that only a few cases are caused by food sensitivity

## SECONDARY (SYMPTOMATIC) THROMBOCYTOPENIC PURPURA

As indicated above thrombocytopenic purpura is often secondary to a generalized disorder of the bone marrow in which the megakaryocytes are actually mechanically



congestive splenomegaly Gaucher's disease Hodgkin's disease Felty's syndrome tuberculosis and sarcoid

## NONTHROMBOCYTOPENIC PURPURA

This type of purpura is characterized by a clinical syndrome milder than the thrombocytopenic variety and associated with normal platelets normal clot retraction and clotting time slight if any disturbance of bleeding time and a positive tourniquet test It may be associated with *infections* (Fig 189) or with drug ingestion and in some instances is associated with *nutritional* deficiency From the standpoint of strict

definition, scurvy is such a nutritional deficiency. In addition to these etiological factors, there are the factor of allergy which is probably the most common one present in nonthrombocytopenic purpura, and the factor of unknown etiology, which has been termed thrombasthenia or pseudohemophilia. The latter term is mentioned only to be condemned for it has been applied to a variety of hemorrhagic diatheses of which nonthrombocytopenic purpura is but one. The term therefore has no definite meaning.

The allergic purpuras bear the names of Schoenlein and Henoch, the former having described a syndrome of purpura associated with arthralgia and an urticaria like eruption and the latter having described a syndrome of purpura and abdominal colic. There is considerable interchange however, between these two clinical syndromes and many patients have both joint involvement and colic. The manifestations may be the result of actual hemorrhage into the joint surface or into the intestinal muscosa. It is difficult, in most cases, to establish the antigen responsible for the purpura. However, many are benefited by elimination diets and by the use of either epinephrine or antihistaminic agents. The prognosis is, in general quite good.

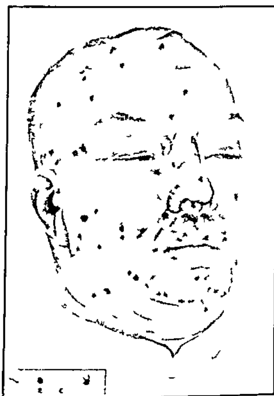


FIG 190 —Photograph and drawing of a patient aged fifty seven years who had suffered with hemorrhages from telangiectases since the age of twenty four. He later developed cirrhosis of the liver. The telangiectasia was familial. Four types of vascular lesions were present. *B* is the typical telangiectasi *D* is a spider angioma. (Wintrobe s Clinical Hematology )

## HEREDITARY HEMORRHAGIC TELANGIECTASIS

This is a hereditary vascular anomaly transmitted as a simple dominant trait involving both sexes and characterized by hemorrhage from the capillaries and venules of the skin and mucous membranes. The disease also bears the names of Osler Rendu and Weber who published early descriptions of it.

The characteristic sign is the presence of

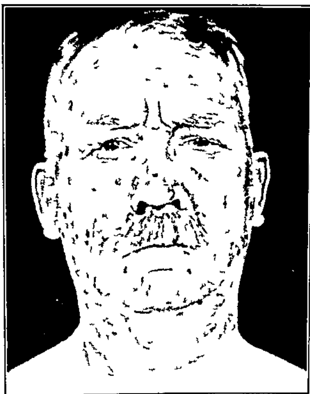
multiple dilatations (telangiectases) of the capillaries and venules on the skin and mucous membranes and in all portions of the body (Figure 190) The family history is almost always positive The symptomatology is that of bleeding from the mucous membranes particularly from the nose There may be an associated anemia as the result of acute or chronic blood loss The treatment usually confines itself to cauterization when the bleeding point is accessible Transfusions may be necessary for acute bleeding and iron may be necessary for anemia of chronic blood loss Death from hemorrhage is rather unusual and life expectancy is in general within normal limits

## DISORDERS OF BLOOD COAGULATION

*Hemophilia —Definition —* This condition is an hereditary abnormality of the blood or blood forming systems It is exhibited only by males but is transmitted through females as sex linked Mendelian factor It is characterized by a chronic liability to hemorrhage which is dependent upon delayed coagulation of the blood

*Etiology —*The cause of the delayed coagulation time in hemophilia is still a source of much controversy One school of thought feels that there is a decrease in a globulin fraction of the plasma which is closely allied to thromboplastin This factor has been called "globulin substance plasma thromboplastin " and anti hemophilic globulin This theory is substantiated by the observation that platelet free plasma both *in vivo* and *in vitro* causes the clotting time of hemophiliacs to return toward normal Another theory is that the disorder is due to the presence of an anticoagulant in the plasma which is quite active against thromboplastin Still a third theory concerns the abnormal stability of the platelets and the failure to release thromboplastin in the course of blood coagulation Almost all recent studies have indicated that hemophilic platelets are quite comparable to normal platelets hence this third theory is at present in moderate disregard

*Incidence —* The disease is relatively uncommon It is transmitted from the male through an unaffected daughter, who is a carrier to a grandson The carrier daughters may also transmit the carrying potentiality to their daughters As a result of recent studies by Brinkhous of a form of hemophilia which occurs in dogs, it has been shown that if a hemophilic male dog mates with a female carrier, a hemophilic female results The absence of truly authenticated hemophilia in the human female is probably the result of the unlikelihood of the marriage of a hemophilic male to a female carrier About a third of all patients fail to give an adequate familial history of hemophilia This may be the result of transmission through several generations of daughters and incomplete knowledge by the patient of the family history or it may be due to an actual mutation



*Symptoms —*The characteristic symptom in hemophilia is the tendency to bleed from minor injuries and spontaneously into joints The excessive bleeding may appear within the first week of life as the result of circumcision Any mild trauma either accidental or intentional, such as a tooth extraction may cause prolonged or even fatal hemorrhage One of the most common and serious complications is hemorrhage into the joints which may result in a permanent deformity Hemorrhage into the joints first of all produces the findings of an acute hemarthrosis with severe pain and swelling and later the symptoms of chronic hemophilic arthritis with flexion deformities and arthralgias The knee joints are most frequently involved and next to these the elbow joints Almost every hemophiliac eventually develops the symptoms of chronic hemophilic arthritis with flexion deformities and muscle atrophy Epistaxis and hematuria are fairly common

*Signs —*Physical examination of the adult hemophiliac usually shows the signs of chronic hemophilic arthritis and there may be evidence of ecchymoses and hematomata and anemia

*Course —*The disease is rather unremitting in its course particularly as far as the hemarthroses and the development of hemophilic arthritis are concerned Adult life expectancy may be only slightly below normal if adequate treatment is given The state-

definition, scurvy is such a nutritional deficiency. In addition to these etiological factors, there are the factor of allergy, which is probably the most common one present in nonthrombocytopenic purpura, and the factor of unknown etiology which has been termed thrombasthenia or pseudohemophilia. The latter term is mentioned only to be condemned, for it has been applied to a variety of hemorrhagic diatheses of which nonthrombocytopenic purpura is but one. The term therefore has no definite meaning.

The allergic purpuras bear the names of Schoenlein and Henoch, the former having described a syndrome of purpura associated with arthralgia and an urticaria like eruption and the latter having described a syndrome of purpura and abdominal colic. There is considerable interchange, however, between these two clinical syndromes and many patients have both joint involvement and colic. The manifestations may be the result of actual hemorrhage into the joint surface or into the intestinal mucosa. It is difficult, in most cases, to establish the antigen responsible for the purpura. Transfusions may be necessary for acute bleeding and iron may be necessary for anemia of chronic blood loss. Death from hemorrhage is rather unusual and life expectancy is in general within normal limits.

## DISORDERS OF BLOOD COAGULATION

*Hemophilia.—Definition.*—This condition is an hereditary abnormality of the blood or blood forming systems. It is exhibited only by males but is transmitted through females as sex linked Mendelian factor. It is characterized by a chronic liability to hemorrhage which is dependent upon delayed coagulation of the blood.

*Etiology.*—The cause of the delayed coagulation time in hemophilia is still a source of much controversy. One school of thought feels that there is a decrease in a globulin fraction of the plasma which is closely allied to thromboplastin. This factor has been called "globulin substance," "plasma thromboplastin" and "anti hemophilic globulin." This theory is substantiated by the observation that platelet free plasma both *in vivo* and *in vitro* causes the clotting time of hemophiliacs to return toward normal. Another theory is that the disorder is due to the presence of an anticoagulant in the plasma which is quite active against thromboplastin. Still a third theory concerns the abnormal stability of the platelets and the failure to release thromboplastin in the course of blood coagulation. Almost all recent studies have indicated that hemophilic platelets are quite comparable to normal platelets, hence this third theory is at present in moderate disregard.

*Incidence.*—The disease is relatively uncommon. It is transmitted from the male through an unaffected daughter who is a carrier to a grandson. The carrier daughters may also transmit the carrying potentiality to their daughters. As a result of recent studies by Brinkhous of a form of hemophilia which occurs in dogs, it has been shown that if a hemophilic male dog mates with a female carrier, a hemophilic female results. The absence of truly authenticated hemophilia in the human female is probably the result of the unlikelihood of the marriage of a hemophilic male to a female carrier. About a third of all patients fail to give an adequate familial history of hemophilia. This may be the result of transmission through several generations of daughters and incomplete knowledge by the patient of the family history, or it may be due to an actual mutation.

*Symptoms.*—The characteristic symptom in hemophilia is the tendency to bleed from minor injuries and spontaneously into joints. The excessive bleeding may appear within the first week of life as the result of circumcision. Any mild trauma, either accidental or intentional, such as a tooth extraction may cause prolonged or even fatal hemorrhage. One of the most common and serious complications is hemorrhage into the joints which may result in a permanent deformity. Hemorrhage into the joints first of all produces the findings of an acute hemarthrosis with severe pain and swelling and later the symptoms of chronic hemophilic arthritis with flexion deformities and arthralgias. The knee joints are most frequently involved and next to these the elbow joints. Almost every hemophiliac eventually develops the symptoms of chronic hemophilic arthritis with flexion deformities and muscle atrophy. Epistaxis and hematuria are fairly common.

*Signs.*—Physical examination of the adult hemophiliac usually shows the signs of chronic hemophilic arthritis and there may be evidence of ecchymoses and hematomata and anemia.

*Course.*—The disease is rather unremitting in its course, particularly as far as the hemarthroses and the development of hemophilic arthritis are concerned. Adult life expectancy may be only slightly below normal if adequate treatment is given. The state-

ment is usually made however, that the *majority of patients do not survive much* beyond childhood

*Diagnosis* —The diagnosis of this disease depends again upon the laboratory findings However the clinical syndrome of hemarthrosis leading to flexion deformities in a male is sufficiently characteristic to permit a clinical diagnosis in many instances

*Complications* —The complications are primarily those of the hemophilic arthritis and hemorrhages due to accidental or intentional trauma It is usually trauma which is responsible for death in most patients with hemophilia

*Laboratory Findings* —The characteristic laboratory finding is that of a delayed venous coagulation time By the Lee and White method, the normal clotting time will be between 4 and 12 minutes The clotting time of a hemophiliac will be from 20 minutes to several hours The results of all the other studies performed in the hemorrhagic diatheses such as bleeding time tourniquet test platelet count and prothrombin times are normal The blood findings are normal except for those which may be the result of acute or chronic hemorrhage The bone marrow examination is normal Tests based upon the ability of normal plasma to correct the deficiency in hemophilia have been devised However these not are usually necessary to establish the diagnosis

*Differential Diagnosis* —The differential diagnosis in hemophilia is primarily from other clinical hemorrhagic diatheses of moderate severity The normal blood findings, except for the greatly prolonged clotting time serve to eliminate most other hemorrhagic diatheses Of the diseases associated with a prolonged clotting time the chief disorders of interest are those of congenital afibrinogenemia and the recently described disorder associated with an anticoagulant

*Treatment* —The only treatment of any avail in hemophilia is the transfusion of relatively fresh blood or plasma or of the globulin fraction of plasma, which has been shown to have antihemophilic properties Use of the latter is still in the experimental stage and is not available for widespread use Relatively small volumes of blood or plasma suffice to shorten the clotting time toward normal, but it returns to its previous delayed time in from 12 to 48 hours In most hemophilic emergencies small transfusions given every 12 hours are usually quite effective in controlling the hemorrhage Larger transfusions are indicated as anemia supervenes The prevention of hemophilic emergencies by repeated transfusion of plasma has recently been attempted Other forms of treatment are the use of topical thrombin for the control of hemorrhage from mild trauma such as tooth extraction

## HYPOPROTHROMBINEMIA

The discovery of vitamin K by Dam in 1934 and of the prothrombin test and the prothrombin defect in jaundice by Quick and his colleagues in 1935 opened an entirely new era in the field of blood coagulation and hemorrhagic diathesis It is now clearly evident that vitamin K is necessary for the production of prothrombin by the liver Vitamin K is a fat soluble material and is found in food it is also synthesized by the bacteria of the intestines Vitamin K requires bile for its absorption Therefore if bile is excluded from the intestinal tract by such mechanisms as biliary obstruction or fistula, inadequate synthesis of prothrombin by the liver will ensue Hypoprothrombinemia may also occur as the result of failure of the newborn to be endowed with adequate amounts of vitamin K and prothrombin by the mother In all instances of hypoprothrombinemia except that associated with liver disease the administration of vitamin K restores the prothrombin concentration of the blood to normal

*Clinical Signs and Symptoms* —The hemorrhagic diathesis of hypoprothrombinemia is for the most part a mild one Ecchymosis and mucous membrane bleeding may be present as well as bleeding into the joints The most serious result of hypoprothrombinemia however is the one which follows major surgery in the absence of previous knowledge of the diminished prothrombin *concentration of the blood* It was this mechanism which accounted for the death of *many patients with jaundice* operated upon before the discovery of vitamin K

*Laboratory Findings and Diagnosis*—The diagnosis of hypoprothrombinemia cannot be made without the actual measurement of the prothrombin concentration of the plasma. Several methods for this determination have been devised. Probably the one devised by Quick or one of its modifications is most frequently used.

*Prevention of Hypoprothrombinemia*—As a result of the knowledge of clinical situations in which hypoprothrombinemia is apt to develop such as obstructive jaundice it is usually possible to prevent hypoprothrombinemia by early administration of vitamin K. In the case of the newborn, the vitamin K may be given to the mother during the last week of pregnancy by the use of the synthetic analogues of vitamin K in a dosage of 1-2 mgms daily by mouth. These may also be given to the newborn parenterally in a dosage of 1-2 mgms. Synthetic vitamin K may also be given in the case of pre-operative preparation of surgical patients. The dosage here need not exceed 2 mgms a day either.

*Treatment*—Once hypoprothrombinemia is discovered by the use of the prothrombin test treatment is indicated and this is best accomplished by the use of vitamin-K synthetic analogues which are water soluble. These can be given orally. The synthetic analogues of vitamin K are of very low toxicity and may be given in relatively large amounts. However in patients with normal liver function a dose not exceeding 10 mgms will usually suffice to bring the prothrombin to normal limits.

## HYPOPROTHROMBINEMIA AND LIVER DISEASE

Both in acute and in chronic liver disease it is often observed that the prothrombin time is prolonged. In this situation vitamin K is usually ineffective. It is this point which makes the use of vitamin K helpful in the differential diagnosis of jaundice. Where the jaundice is due to biliary obstruction and liver disease has not had an opportunity to develop the low prothrombin concentration will probably increase upon the administration of vitamin K. On the other hand where jaundice is due to hepatocellular disease the administration of vitamin K will be ineffective. The only therapy for the hypoprothrombinemia of liver disease is the transfusion of fresh blood or plasma.

*Hypoprothrombinemia and Dicumarol*—The discovery of dicumarol by Link and the hypoprothrombinemia produced by this agent represents a significant advance in the treatment of thromboembolic disease. Dicumarol because of its chemical resemblance to vitamin K competes with it in the liver synthesis of prothrombin and results in hypoprothrombinemia. This hypoprothrombinemia is useful in the treatment of coronary thrombosis or other thromboembolic diseases.

It is important to bear in mind that the administration of dicumarol must be followed up by the taking of daily prothrombin times for the effects of the drug may not manifest themselves for from 48 to 72 hours. During this time the drug may accumulate and cause serious hemorrhage unless it is administered with circumspection. The effectiveness of vitamin K preparations in the treatment of hypoprothrombinemia due to dicumarol toxicity is still somewhat in controversy. In general the best treatment aside from the obvious one of discontinuing the drug is the administration of fresh blood or plasma. Here too it is important to note that prothrombin concentration of the blood will rise rather slowly after the discontinuance of dicumarol and that there may be a latent period of 2 or 3 days before it begins to rise at all.

TABLE 62—CLASSIFICATION OF HEMORRHAGIC DISEASES ACCORDING TO PATHOLOGIC PHYSIOLOGY

- Failure of Vascular Defense (bleeding time usually increased and tourniquet test usually positive)
  - Thrombocytopenic Purpura (platelets decreased, clot retraction poor)
    - Idiopathic (Werlhof's disease: diminished formation of platelets from megakaryocytes in marrow; megakaryocytes usually normal or increased; eosinophils may be increased in marrow and blood)
    - Toxic or Allergic (history of drug ingestion, infection or hypersensitivity)
    - Secondary (symptomatic)
      - Disease of Bone Marrow (megakaryocytes mechanically displaced)
        - Leukemia
        - Pernicious anemia

Aplastic anemia
Chronic hypochromic anemia
Tuberculosis
Carcinomatosis
Lymphomatosis etc
Disease of Spleen (hypersplenism spleen almost invariably enlarged megakaryocytes in marrow present in normal numbers)
Congestive splenomegaly
Gaucher s disease
Felty s syndrome
Lymphomatosis
Tuberculosis
Sarcoid etc
Non thrombocytopenic Purpura (platelets normal clot retraction good)
Allergic
Henoch s purpura (*gastro-intestinal colic*)
Schonlein s purpura (rheumatic symptoms)
Toxic (drugs, uremia)
Infections (septicemias)
Nutritional (scurvy)
Thrombasthenia (usually hereditary)
von Willebrand s disease
Glanzmann s disease
Hereditary Hemorrhagic Telangiectasia
Osler Rendu Weber disease
Failure of Blood Coagulability Defense (venous clotting time usually increased)
Hemophilia (probably thromboplastin deficiency Prothrombin time normal exclusively in males sex linked Mendelian recessive hemarthroses common)
Hypoprothrombinemia (prothrombin time prolonged venous clotting time frequently normal)
Failure of Vitamin K Absorption (responds to vitamin K)
Due to exclusion of bile from intestine
Biliary obstruction
Biliary fistula
Due to Intestinal disease
Sprue
Colitis
Ileitis etc
Failure of Synthesis of Vitamin K by Intestinal Flora (responds to vitamin K)
Hemorrhagic disease of newborn
*Failure of Production of Prothrombin by Liver* (does not respond to vitamin K)
Cirrhosis
Hepatitis
Acute yellow atrophy
Fibrinogenopenia (absence of fibrinogen must be demonstrated by analysis)
Congenital
Acquired (liver disease)
Factor V Deficiency (disease described by *Owren*)
Circulating Anticoagulant (patient s plasma is anticoagulant for normal blood)
Heparin or Heparin like Substance (anaphylactic shock ? of irradiation)
Unknown (Disease described by Lozner Jolliffe and Taylor)

## CHRONIC CONGESTIVE SPLENOMEGALY (BANTI'S DISEASE)

By Cyrus C Sturgis, M D

*Synonyms* —Splenic anemia Fibrocongestive splenomegaly

*Definition* —This condition is a syndrome probably resulting from a circulatory disturbance of the spleen which is characterized by chronicity, a tendency to bleeding from the gastro intestinal tract splenomegaly, leukopenia frequently thrombocytopenia evidences of an increased collateral circulation between the portal and peripheral venous circulation and by certain constant anatomic changes in the spleen

*Etiology* —The cause of the syndrome is obscure Banti's original theory that it resulted from the action of some unknown toxic agent first on the spleen and later on the liver is no longer accepted It is probable that several causes may lead to one common result which is responsible for the condition William P Thompson believes that it is due to the mechanical obstruction of the blood from within the portal system which produces secondary congestive splenomegaly The obstruction may result from hepatic cirrhosis or to a variety of extrahepatic causes as thrombosis of the portal and splenic veins, compression of the veins by tumors or scars stenosis of the portal vein and possibly other developmental defects Ravenna suggests that the splenic congestion may be caused by lesion of the splenic arterioles which produce a circulatory disturbance in the portal bed

Regardless of the cause, the changes in the spleen are the same namely follicular atrophy fibrosis of the pulp with dilated venous sinuses the characteristic perifollicular hemorrhage and siderotic nodules

*Symptoms and Signs* —The condition usually appears before the age of thirty five years but may develop in childhood It is somewhat more common in females There is no hereditary tendency

The onset is usually gradual with the symptoms of anemia chiefly weakness ease of fatigue and pallor Commonly vague digestive complaints as abdominal discomfort and distention appear There may be diarrhea Enlargement in the upper left quadrant of the abdomen may be the first indication to the patient of the disorder or a large hematemesis or passage of tarry stools may inaugurate the disease Gross gastro intestinal bleeding occurs in about 50 per cent of the cases

Physical examination usually shows a moderate splenomegaly but in some instances the organ may be enormous filling the entire left side of the abdomen About one-third of the cases have moderate enlargement of the liver

*Blood* —An anemia averaging about 3,500 000 red blood cells per c mm is commonly present, and usually it is normocytic in type If there have been repeated hemorrhages it will be of the microcytic hypochromic variety With extensive involvement of the liver and in the absence of bleeding it may be of the macrocytic type

A leukopenia of less than 5000 cells per c mm and characterized by a reduction of all types of cells is almost always present and represents therefore one of the most constant findings of the disease There is often a moderate reduction in the number of platelets and sometimes they may be below 100 000 per c mm Occasionally evidence of a thrombocytopenic purpura may be present

*Prognosis and Treatment* —In many patients there are long periods of good health without manifestations of the disease Massive bleeding, however is unpredictable as it may occur at any time without warning Death results from bleeding liver insufficiency' or intercurrent disease

Treatment of the anemia includes transfusions following excessive hemorrhage iron if a microcytic hypochromic anemia is present and intramuscular injections of liver extract in a few patients who have a macrocytic anemia The diet should be high in protein and may be supplemented by yeast

The decision concerning splenectomy is the one which is difficult to make as the value of this procedure is not uniformly acknowledged A comparison of the course of the disease in patients in whom the operation has been performed has been said to

Aplastic anemia
Chronic hypochromic anemia
Tuberculosis
Carcinomatosis

## MALIGNANT LYMPHOMAS

By CYRUS C. STURGIS, M.D.

*Classification.* — The classification of the lymphomas is confused: the clinical characteristics of the subtypes are not clean cut, and a histologic basis for differentiation is unreliable because a lymphoma may change from one type to another, vary from one lymph node to another or vary in type within the same lymph node.

*Interrelation Between Hodgkin's Disease and Other Lymphatic Tumors.* —Custer and Bernard (1948) after studying the interrelationship between Hodgkin's disease and other malignant lymphomas concluded that the cellular structure of the tumors was extremely labile, transitions from one type to another occurring frequently. The predominating cell pattern at any one examination may indicate one of the three forms of Hodgkin's disease (paragranuloma, granuloma or sarcoma), follicular lymphoblastoma, lymphosarcoma, reticulum-cell sarcoma, lymphatic leukemia or monocytic leukemia. *They believe that these terms are useful only to designate the predominating histologic pattern of a lymphoma at any one time. A rigid classification of lymphatic tumors therefore is not warranted. The entire group in their opinion may be regarded as a single neoplastic entity having a number of variants.*

Terms employed to designate the cellular pattern of a lymphoma at any given time are as follows:

1. Hodgkin's granuloma, paragranuloma and sarcoma (defined under Hodgkin's disease).
2. Follicular lymphoma (a lymphatic tumor, localized or multicentric, in which there is differentiation into follicles).
3. Lymphosarcoma (a tumor consisting of relatively uniform round cells, which may be small, well differentiated lymphocytes or large immature lymphocytes).
4. Reticulum-cell sarcoma (a tumor made up of very large cells with big nuclei. This type has been called "stem-cell lymphoma," "clasmatocytic lymphoma," etc. to indicate the highly undifferentiated form of the cells observed in this disease).
5. Mycosis fungoides, a condition now generally regarded as a neoplasm accompanied by tumor-like changes in the skin and ultimate histologic evidence of involvement of the superficial and deep lymph nodes, the bone marrow and other tissues with Hodgkin's disease, lymphosarcoma or lymphatic leukemia. The form usually encountered develops after a premycotic lesion characterized by a desquamative dermatitis with pruritus which may in some cases precede by years the formation of cutaneous tumors; on the other hand, the tumors may be the initial evidence of a lymphoma. The tumors are raised purplish red areas of infiltration usually exceeding three cubic centimeters in diameter. Ulceration occurs late in the disease.

## HODGKIN'S DISEASE

*Synonyms.* — Pseudoleukemia. Lymphoblastoma. Malignant lymphoma. Malignant lymphogranuloma. Lymphadenoma.

*Definition.* —A fatal disease, sometimes of long duration, of undetermined cause but most likely neoplastic or infectious in nature, characterized by typical histologic changes in lymph glands, spleen and other organs, by a painless, progressive, radiosensitive enlargement of lymph glands and, in the advanced stages, by fever, anemia and emaciation.

*Etiology.*—It is well recognized that the disease is observed in all races and is about twice as frequent in males as in females. It may occur in infancy and in extreme old age but the greatest incidence is in the third decade. The cause has been attributed to various types of infection including tuberculosis and an unidentified virus but it is now considered to be neoplastic in origin by a majority of students of the disease. Others believe however that it is of totally unknown origin.

*Relation to Tuberculosis.*—Between 15 and 20 per cent of all patients with Hodgkin's disease also have tuberculosis, but the cause of this association is not known. Furthermore in 80 to 85 per cent of the patients with Hodgkin's disease there is an anergy to tuberculin as evidenced by a negative tuberculin reaction. The presence of a positive reaction with tuberculin in high dilution in an untreated patient is evidence of active tuberculosis. The frequent association of the two diseases is possibly on the basis that Hodgkin's disease predisposes to tuberculosis or that the constitutional type which is predisposed to Hodgkin's disease also is more susceptible to infection with the tubercle bacillus.

*Pathology.*—There is usually a widespread involvement of both the superficial and deep lymph glands including the cervical, axillary, inguinal, mediastinal and abdominal glands. In size they vary from that of a pea to an orange. They are round, smooth, hard or soft depending on the stage of the disease and loosely held together with connective tissue. The glands are never firmly adherent to each other unless there has been a secondary infection. The characteristic microscopic picture is one of lymphoid hyperplasia with active proliferation of the germinal centers and the endothelial and reticular cells. Multinuclear giant cells and eosinophils are frequently observed. As the process advances there is an increase in connective tissue until the cellular part of the tumor is reduced to small areas lying between bands of fibrous tissue. While the condition primarily involves the lymph glands almost any organ of the body containing lymphatic tissue may develop the characteristic changes. The process is noted commonly in the spleen and less frequently in the liver and kidneys. The bone marrow may be infiltrated with lymphoid cells which in large part replace the erythroblastic tissue and thus produce a myelophthisic anemia.

Jackson and Parker have divided Hodgkin's disease into three subgroups: (1) Hodgkin's granuloma, the familiar type (90 per cent of all cases), the duration of life being a few years with the usual clinical picture. (2) Hodgkin's paragranuloma (the disease usually becomes apparent in the neck glands and runs a benign course; the histologic picture in the glands does not resemble true tumor). (3) Hodgkin's sarcoma (a true neoplasm as it is invasive). Hodgkin's sarcoma occurs most commonly in the fifth and sixth decades, rarely before thirty years of age. The life expectancy is brief.

*Symptoms.*—The most frequent initial symptom is a painless unilateral enlargement of a cervical lymph gland although the primary glandular enlargement may be in the axilla or inguinal regions or in the abdomen. The involvement often spreads rapidly to the other side of the neck and other superficial lymph glands. The enlarged nodes are usually firm, freely movable, not adherent to the skin or other glands and nontender. Occasionally however the earliest evidence of the condition may be loss of weight and weakness, fever, pruritis or cough and dyspnea.

As the disease progresses certain constitutional symptoms inevitably appear. Such complaints as weakness, loss of weight, pallor, dyspnea and palpitation are due entirely or in part to the associated myelophthisic anemia. Fever is present during the course of the disease in all cases. A striking type of the disease shows febrile periods persisting for two or three weeks alternating with afebrile periods of a week or ten days duration (Pel-Ebstein type). The presence of this type of fever, an anemia and leukopenia is suggestive of the diagnosis of Hodgkin's disease in the absence of other obvious cause of such changes.

A large variety of symptoms may result from the pressure of the enlarged glands upon nerves, blood or lymph vessels or various organs. Enlarged glands in the

be no different than in those who have not been operated upon. Certainly if there is evidence of extensive liver damage, the operation can do little good. In the absence of evidence of severe hepatic injury, an abdominal exploratory operation should be seriously considered and splenectomy performed if the liver appears to be reasonably normal in appearance.

4. *Reticulum-cell sarcoma* (a tumor made up of very large cells with big nuclei. This type has been called "stem cell lymphoma," "*clasmatocytic lymphoma*," *etc. to indicate* the highly undifferentiated form of the cells observed in this disease).

5. Mycosis fungoides: a condition now generally regarded as a neoplasm accompanied by tumor-like changes in the skin and ultimate histologic evidence of involvement of the superficial and deep lymph nodes, the bone marrow and other tissues with Hodgkin's disease, lymphosarcoma or lymphatic leukemia. The form usually encountered develops after a premycotic lesion characterized by a desquamative dermatitis with pruritus, which may in some cases precede by years the formation of cutaneous tumors; on the other hand, the tumors may be the initial evidence of a lymphoma. The tumors are raised, purplish red areas of infiltration usually exceeding three cubic centimeters in diameter. Ulceration occurs late in the disease.

## HODGKIN'S DISEASE

*Synonyms.*—Pseudoleukemia. Lymphoblastoma. Malignant lymphoma. Malignant lymphogranuloma. *Lymphadenoma.*

*Definition.*—A fatal disease, sometimes of long duration, of undetermined cause but most likely neoplastic or infectious in nature, characterized by typical histologic changes in lymph glands, spleen and other organs, by a painless, progressive, radiosensitive enlargement of lymph glands and, in the advanced stages, by fever, anemia and emaciation.

plasma-cell infiltration In late cases, there may be hypoplasia of erythropoiesis

*Blood* —The blood changes are not sufficiently constant or characteristic to be of great aid in diagnosis In about a third of our patients, when first seen there was no anemia In the rest, there was slight or moderate progressive anemia, most frequently of the hypochromic normocytic type but in about 20 per cent of the hypochromic microcytic variety The red blood cells usually appear quite normal unless the anemia is severe An acquired hemolytic anemia with some degree of macrocytosis, the latter probably being associated with the presence of reticulocytes in the circulating blood is occasionally observed The white blood-cell count is normal or within 10 per cent of normal in almost all patients In some however it may be increased to 25 000 per cubic millimeter or even higher and in others a leukopenia with a white blood cell count as low as 2000 per cubic millimeter may be present, even in the absence of roentgen ray therapy A leukopenia is usually associated with the more advanced phases of the disease and may portend an ominous outlook

The two most common alterations on examination of a stained blood film are (1) an increase in the neutrophil percentage with a greater number of nonsegmented forms (this occurs almost constantly) and (2) an eosinophilia of greater than 10 per cent (this has however rarely been known to reach 70 per cent or more) There are frequently a relative lymphopenia and a monocytosis The platelets tend to parallel the white blood cell count and hence may be increased or decreased The sedimentation rate is almost always elevated when the disease is active The bone marrow shows no characteristic findings and hence from a diagnostic standpoint, its chief value is in ruling out leukemia

*Prognosis* —It is generally considered that Hodgkin s disease terminates fatally 2 or 3 years after the clinical onset In my opinion early treatment with roentgen ray and nitrogen mustards will frequently prolong life to an average of between 4 and 5 years although not all observers agree Experience has shown that almost 20 per cent of the patients will survive for at least 5 years and 5 per cent for 10 years, I have even observed a patient who was alive 21 years after the diagnosis of Hodgkin s disease had been established All agree that there is a wide variation in the length of life after onset of the disease the reason for this is unknown but it probably depends on some obscure inherent tendency of the disease process Patients with involvement limited to the upper cervical regions who receive early treatment do the best Those with palpable spleen and a white blood-cell count below 6000 or above 10 000 per cubic millimeter and those with anemia have the most unfavorable outlook When the syndrome of a Pel Ebstein fever, leukopenia and anemia is present the chances for survival of more than a few months is not great

*Pregnancy and Hodgkin's Disease* —In many cases Hodgkin s disease has apparently not interfered with pregnancy or the delivery of a normal child Roentgen ray therapy should be withheld during pregnancy to avoid harming the child *in utero* probably the only safe form of therapy for Hodgkin s disease in cases of pregnancy is blood transfusions

*Treatment* —Radical excision of the glands has been advised in the past but there are few advocates of this form of therapy at present Localized symptomatic roentgen-ray treatment is the treatment of choice and it is undoubtedly of great service It alleviates symptoms increases the survival period diminishes the size of the glands and improves the patient's sense of well being Roentgen ray therapy should be given when there is fever, anemia gland enlargement causing pressure on nerves or vital organs or apparent progression of any lesion The idea previously held that after a certain amount of roentgen therapy the patient became refractory to it is not necessarily true In my opinion the refractoriness develops as a result of progression of the disease regardless of the amount of $x$ ray therapy employed There is no evidence that radium is superior Radioactive elements such as phosphorus are not indicated Blood transfusions are of great value and should be given frequently in an attempt to maintain the hemoglobin at a minimum

mediastinum may cause the clinical picture of a mediastinal tumor with dyspnea cyanosis distention of the veins of the neck and edema of the face The trachea may be compressed and deviated Occasionally a patient is observed in whom the outstanding features are splenomegaly a moderate anemia, and fever Usually, however splenomegaly is not present unless the disease is advanced Dysphagia is not uncommon and pressure on the recurrent laryngeal nerves may result in aphonia Jaundice may be present as the result of pressure on the common bile duct by enlarged lymph glands, or in association with direct invasion of the liver by the pathologic process When a discharging sinus develops from a gland, which is rarely it is usually due to a concomitant tuberculosis

Abdominal symptoms are common and are the initial ones of the disease in some patients Abdominal pain simulating gallbladder disease or peptic ulcer may be present Additional complaints are diarrhea or constipation distention and diffuse abdominal tenderness The basis for these may occasionally be either multiple small ulcers of the stomach and bowel or infiltration of the wall in the areas affected The mediastinum the lung parenchyma the hilar nodes, and the pleura with or without an accumulation of fluid may be affected the greatest incidence of involvement being in the order named The possibility of a complicating amyloidosis should be kept in mind if an excessive amount of protein appears in the urine or a generalized anasarca develops in a patient with Hodgkin s disease Osteolytic or less commonly osteoblastic granulomatous foci occur in from 5 to 15 per cent of the patients These are more frequently observed in the order named vertebral column pelvis ribs upper ends of the femurs and the sternum Pain in the back either with or without erosion of the spine is occasionally a prominent symptom and may arise from spinal nerve root involvement A spastic paraplegia has been known to occur from invasion or compression of the spinal cord Pain in the legs is a common symptom late in the disease but it may occur early In Hodgkin s granuloma the neurological involvement arises by extension from the cranial bones or vertebræ to the dura, or from the development of an epidural tumor without bone lesions There are no proved cases in which the substance of the brain has been involved primarily, although this may occur in patients with Hodgkin's sarcoma, reticulum-cell sarcoma or lymphatic leukemia Cutaneous manifestations occur in about one-third of the patients, although often they are of minor significance An extreme degree of pruritus may be an early and annoying symptom which sometimes constitutes the patient s chief complaint In some patients there may be a generalized brownish pigmentation, or the discoloration may be irregularly distributed giving a mottled appearance Occasionally there may be an actual infiltration of the skin producing small nodules, or a generalized exfoliative dermatitis, or purplish-red tumor like cutaneous masses These masses are like those characteristic of the syndrome of mycosis fungoides

*Diagnosis* —The presence of a painless enlarged lymph gland appearing without obvious cause, should at once suggest the possibility of Hodgkin s disease In all such cases a small gland should immediately be excised and examined microscopically by a competent pathologist The patient should be carefully examined for evidence of other glandular enlargement including roentgenograms of the chest to determine the presence or absence of enlargement of the mediastinal glands In some, the clinical picture may be that of chills and fever without obvious cause In such patients there is usually enlargement of the superficial lymph glands but this may not occur until late in the disease Others have splenomegaly and a hypochromic anemia without superficial glandular enlargement which suggests the possibility of Banti s disease

*Sternal Aspiration* —Marrow thus obtained does not show specific changes and is of chief value in ruling out leukemia although the findings have some confirmatory value in suspicious cases The marrow is usually cellular and the myeloid-erythroid ratio is normal The myeloid cells show a shift to the left, which is evidence of immaturity There is an eosinophilic and

## AGRANULOCYTOSIS

By Cyrus C Sturgis M D

*Synonyms* —Agranulocytic angina Malignant neutropenia Acute granulopenia Granulocytopenia

*Definition* —Agranulocytosis is a disease almost always due to a drug sensitivity, characterized by secondary infection with chills fever and ulcerative lesions in the mouth throat rectum vagina and sometimes elsewhere in the body There is a remarkable reduction or complete disappearance of the polymorphonuclear cells in the peripheral blood and in untreated patients often a rapidly fatal course

*Etiology* —The disease most commonly affects adults between the ages of 25 and 65 years and females twice as commonly as males Children occasionally have the condition as do infants one having been reported with the disorder possibly due to sepsis on the third day of life

Roberts and Kracke have presented a logical theory concerning the mechanism of the production of the disease as follows (1) there is the onset in the bone marrow with a failure of myelocytic function which may be due to myelocytic aplasia or cessation of maturation (maturation arrest) (2) after a few days there is a gradual diminution of the granulocytes in the peripheral blood until they may disappear or number only a few hundred per c mm (3) there is the clinical onset with the appearance of the characteristic symptoms (4) with the loss of protection bacterial invasion begins (5) recovery, or death follows

It has been suggested that the initial failure of the bone marrow which is the fundamental basis for the disease is due to sepsis, allergy or some endocrine disturbance There is little evidence to support these theories and it has now been firmly established that the condition is almost always the result of a sensitivity to drugs The following have been established as unquestionably causing the disease in patients who have a sensitivity to them (1) the sulfonamide drugs including prontosil sulfanilamide sulfapyridine sulfathiazole sulfadiazine succinyl sulfathiazole sulfaguanidine and sulfamerazine (2) thiourea and derivatives as thiouracil propylthiouracil and methylthiouracil (3) aminopyrine and closely related drugs as novaldin and causalin (4) gold (5) dinitrophenol (6) organic arsenicals as arsphenamine neoarsphenamine and mapharsen (7) presidon (pyrithyldione) (8) antihistaminic drugs as pyribenzamine diatrin and possibly other closely allied preparations (9) mustard gas (10) urethane Of alleged etiologic relationship but probably rarely if ever the cause of the condition are the barbiturates antipyrine neostibosan quinine and quinidine bismuth nirvanol plasmoquin trinitrotoluene chloromycetin tridione and mesantoin The two latter employed in convulsive states may cause a moderate selective depression of the granulocytes in the peripheral blood and, in severe involvement an aplastic anemia They do not however cause the typical syndrome of agranulocytosis

It should be recognized that the drugs known to cause the disease do so only in an exceedingly small percentage of the patients to whom they are given It must be assumed therefore that these substances can produce

level of approximately 11.0 grams per 100 cc of blood (70 per cent) Arsenic in the form of Fowler's solution may be employed as in myelogenous leukemia, but the results are greatly inferior to irradiation

*The Nitrogen Mustards* —The introduction of these preparations has been a distinct advance in the treatment of Hodgkin's disease and allied disorders The most commonly used members of this group are methyl bis (betachloroethyl) amine hydrochloride, or HN 2, and S K 136 which is a double nitrogen mustard thought to have the same effect Although the latter produces toxic effects less frequently they are more severe and prolonged when they do occur, even toxic psychoses have been noted The dose of each preparation is 0.1 milligram per kilo of body weight the dose to be given intravenously by injecting it into the rubber tubing of a free flowing intravenous saline-infusion set to avoid irritation of the vein and the surrounding tissue Such an injection is given every other day for four doses but in no instance should the total of the four doses exceed 24 milligrams The mode of action is similar to that of the roentgen rays and at present is thought to be chiefly a reaction with some nuclear component of the cell The treatment has been employed with success in various types of lymphoid disorders especially in Hodgkin's disease lymphosarcoma, follicular lymphoblastoma mycosis fungoides, and reticulum cell sarcoma

The indications for use of the nitrogen mustards in Hodgkin's disease and allied disorders are (1) the presence of the generalized form in which some of the involved areas are inaccessible to irradiation (2) The futility of further roentgen therapy (3) a white blood-cell count of 3500 per cubic millimeter or higher (4) the presence or threat of post irradiation changes (5) involvement of the nervous system or obstructive mediastinal tumors (post irradiation swelling undesirable)

The favorable effects of the nitrogen mustards may appear within a few days There is prompt recession of the enlarged lymph nodes and the spleen the fever itching cough, chest pain, and central nervous-system symptoms often disappear and the general condition of the patient improves promptly Mediastinal enlargements pleural effusions and ascites are more resistant The effects are purely palliative as the duration of the improvement may be limited to as short a time as one month, although in other patients, the improvement may last for several months or a year or longer There is clear evidence that an additional therapeutic effect may be attained by nitrogen mustard after roentgen ray therapy is no longer effective Furthermore, it is thought by some that patients refractory to x ray may become resensitized to this agent by nitrogen mustard There is also some evidence to suggest that the roentgen rays may re ensitize a patient resistant to nitrogen mustard

*Toxic Effects and Contraindications to Nitrogen Mustards* —Nausea and vomiting follow treatment in almost every patient They may occur after some injections and not after others Rarely do they persist for longer than 8 hours except occasionally when S-K 136 is given Gastrointestinal bleeding has seldom occurred In a few instances, mild anemia and thrombocytopenia have developed The limiting factor to the treatment is the leukopenia which may become extreme within a few days falling to as low as 400 white blood cells per cubic millimeter It is not advisable to employ this form of treatment when the white blood cell count is below 3500 per cubic millimeter

Recently Pearson and his associates (1949) have administered ACTH and cortisone in four divided doses totaling from 100 to 200 milligrams daily to a group of patients with lymphoid tumors In six patients there was a dramatic and progressive decrease in the size of the enlarged lymph nodes and of the enlarged spleens but in none of the patients was a complete clinical remission obtained These studies have not however established the efficacy of ACTH and cortisone as therapeutic agents in these conditions and the likelihood that they will produce only temporary benefit is great

## AGRANULOCYTOSIS

By Cyrus C Sturgis M D

*Synonyms* —Agranulocytic angina Malignant neutropenia Acute granulopenia Granulocytopenia

*Definition* —Agranulocytosis is a disease almost always due to a drug sensitivity characterized by secondary infection with chills fever and ulcerative lesions in the mouth throat rectum vagina and sometimes elsewhere in the body There is a remarkable reduction or complete disappearance of the polymorphonuclear cells in the peripheral blood and in untreated patients often a rapidly fatal course

*Etiology* —The disease most commonly affects adults between the ages of 25 and 65 years and females twice as commonly as males Children occasionally have the condition as do infants one having been reported with the disorder possibly due to sepsis on the third day of life

Roberts and Kracke have presented a logical theory concerning the mechanism of the production of the disease as follows (1) there is the onset in the bone marrow with a failure of myelocytic function which may be due to myelocytic aplasia or cessation of maturation (maturation arrest) (2) after a few days there is a gradual diminution of the granulocytes in the peripheral blood until they may disappear or number only a few hundred per c mm (3) there is the clinical onset with the appearance of the characteristic symptoms (4) with the loss of protection bacterial invasion begins (5) recovery, or death follows

It has been suggested that the initial failure of the bone marrow which is the fundamental basis for the disease is due to sepsis allergy or some endocrine disturbance There is little evidence to support these theories and it has now been firmly established that the condition is almost always the result of a sensitivity to drugs The following have been established as unquestionably causing the disease in patients who have a sensitivity to them (1) the sulfonamide drugs including prontosil sulfanilamide sulfapyridine sulfathiazole sulfadiazine succinyl sulfathiazole sulfaguanidine and sulfamerazine (2) thiourea and derivatives as thiouracil propylthiouracil and methylthiouracil (3) aminopyrine and closely related drugs as novaldin and causalin (4) gold (5) dinitrophenol (6) organic arsenicals as arsphenamine neoarsphenamine and mapharsen (7) presidon (pyrithyldione) (8) antihistaminic drugs as pyribenzamine diatrin and possibly other closely allied preparations (9) mustard gas (10) urethane Of alleged etiologic relationship but probably rarely if ever the cause of the condition are the barbiturates antipyrine neostibosan quinine and quinidine bismuth nirvanol plasmoquin trinitrotoluene chloromycetin tridione and mesantoin The two latter employed in convulsive states may cause a moderate selective depression of the granulocytes in the peripheral blood and in severe involvement an aplastic anemia They do not however cause the typical syndrome of agranulocytosis

It should be recognized that the drugs known to cause the disease do so only in an exceedingly small percentage of the patients to whom they are given It must be assumed therefore that these substances can produce

the disease only in persons who are sensitive to them.

There is a remarkable form called *recurrent or cyclic agranulocytosis* in which the episodes have the identical clinical and hematological aspects of the acute attacks. Such a condition is rare. It occurs at all ages from infancy to old age and appears to predominate in females. It is characterized by recurrent attacks every two or three weeks of fever, chills, and ulcerative lesions in the mouth and throat, with a striking decrease in the total white blood cell count and a reduction or complete disappearance of the neutrophils from the circulating blood. These attacks may occur over a long period; the longest such period on record is 34 years. The attacks have been attributed to cyclic infections, to endocrine disturbances, to deficiency in some factor controlling the development of the neutrophils in the bone marrow, but none of these explanations has been substantiated. Apparently the attacks are not associated with sensitivity to any type of medication, and overactivity of the spleen is not the cause (though improvement may follow splenectomy).

A *chronic* type of *agranulocytosis* has been described in which the manifestations are vague, consisting mainly of chronic fatigue and weakness associated with only a moderate depression of the white-blood cell count and neutrophil percentage. Such a condition, however, is rare and the clinical picture is ill defined.

*Primary splenic neutropenia* is a condition in which the total white blood cell count and neutrophil percentage may be greatly reduced over a long term of years (Wiseman and Doan 1939). It should not be confused with agranulocytosis, for primary splenic neutropenia is probably due to hypersplenism, which results in some cases in a selective destructive action on the neutrophils of the circulating blood with a resultant granulocytopenia. In such cases there are (1) splenomegaly, (2) neutropenia, (3) unimpaired production of neutrophils in the bone marrow, and (4) demonstration of splenic overactivity by the epinephrine test. Splenectomy usually affords relief.

*Symptoms and Signs*.—The clinical picture of acute agranulocytosis is that of a combination of sepsis of varying intensity but often severe, with ulcerative lesions of the mucous membranes, *usually of the mouth* and throat but sometimes of the vagina and rectum or other areas. The onset may be abrupt, with *fever, chills, sore* throat, and extreme prostration. Delirium may appear early. The ulcerative lesions may also occur throughout the entire alimentary tract, from esophagus to anal canal. Such lesions are not infrequently in the vagina and on the vulva; in a few instances they have been found on the conjunctiva. Often the condition is a fulminating one, but occasionally there may be only slight soreness of the throat with a mild febrile reaction. Necrosis of the skin is a rare complication, as is jaundice. The latter is due to hepatitis and gives an unfavorable prognosis.

The liver and spleen are not enlarged, and there is no generalized adenopathy, but the lymph glands draining the ulcerative lesions in the mouth and throat are usually enlarged and tender. In about half the fatal cases, there is evidence of a bronchopneumonia. This is a common cause of death, especially among the older patients.

*Blood*.—The striking feature is a pronounced leukopenia which may progress to such an extent that the polymorphonuclear *neutrophil cells completely disappear from* the peripheral blood. The reduction at first is only in the granulocytes, but later the *lymphocytes and monocytes* are also diminished. The total leukocyte count may be reduced to a few hundred cells per cubic millimeter. There is no alteration in the red blood cells unless a preexisting anemia is present or the illness is long continued, and then a slight to moderately severe anemia with a low color index may develop. The platelets are usually normal or increased except when the illness is prolonged, and they may then become diminished.

*Sternal Aspiration*.—The bone marrow shows either *myeloblastic hyperplasia* with arrest of maturation at the promyelocytic myelocytic stage but with normal erythropoiesis and thrombopoiesis, or *aplasia of the granulocytic system* with little involvement of the precursors of the erythrocytes or platelets. In the latter condition the prognosis is poor.

*Diagnosis*—The diagnosis is based upon the occurrence of a brief illness with an acute onset in an adult who has ingested one of the known causative agents and develops sepsis and ulcerative lesions of the mucous surfaces With these symptoms there is a decrease in circulating granulocytes which exceeds any other condition observed in clinical medicine and an *absence* of splenomegaly hepatomegaly immature white corpuscles in the blood stream, and a severe anemia It is most frequently confused with the leukopenia of severe sepsis aplastic anemia and subleukemic leukemia

*Prognosis and Treatment*—Agranulocytosis must always be considered a serious disease in which the outlook is ominous unless adequate and early treatment is given In the earlier series of cases the mortality rate was approximately 75 per cent but with effective treatment it was reduced to 25 per cent At present with the energetic use of anti biotic preparations to combat infection the outlook is greatly improved If the patients are seen early and the proper therapeutic measures are instituted promptly, the condition is seldom fatal There is an equal mortality in the two sexes

The most serious outlook is for patients over sixty The best prognostic indication is the general condition of the patient The following manifestations however have a serious significance—delirium extreme prostration necrotic lesions of the skin pneu monia jaundice a leukocyte count below 1000 per c mm or a complete absence of polymorphonuclear cells from the blood stream

The two most important aspects of treat ment are (1) discovering and eliminating the drug causing the condition and (2) treating the complicating infection early and efficiently with antibiotic preparations The diagnosis established a culture should be obtained at once from the patient s mouth and blood stream the organism isolated and sensitivity tests with the various anti biotics performed Without waiting for the results of these studies energetic antibiotic treatment should be instituted Since the mouth organisms are usually staphylococci and streptococci 400 000 units of penicillin should be given intramuscularly every 4 hours (2 4 million units every 24 hours) In addition if the patient is elderly or in an obviously serious condition 0 5 gram of aureomycin in 500 cc of normal saline solution should be injected intravenously by the slow drip method every twelve hours The penicillin should be continued in the dosage indicated above till the patient s temperature has been normal for at least 4 or 5 days and his general condition has greatly improved After a few days the aureomycin may be given orally (2 0 to 4 0 grams a day in capsules) If these preparations do not benefit the patient the results of the sensitivity tests should serve as a guide to further therapy In some cases streptomycin chloromycetin terramycin or other preparations may be indicated

The patient s tendency to recover spontaneously after the causative drug has been eliminated has confused the claims for various forms of therapy In my opinion however there is no convincing evidence that pentnucleotide, folic acid pyridoxine yellow bone marrow concentrate liver extract or stimulating doses of roentgen ray are of value If the patient s course is downhill I would not hesitate to give 2 or 3 blood transfusions of 500 cc each they may be helpful and can do no harm I would not use sulfonamide drugs in some cases they may cause agranulocytosis Besides the antibiotic preparations are more effective and have fewer side effects

The local treatment of the infected mouth and throat should be only with mouth washes and gargles of warm normal saline solutions Radical measures are to be avoided The fluid intake should be maintained adequately by intravenous saline and 5 per cent glucose injections if necessary The diet should be liquid or soft

*Prevention of Agranulocytosis*—When a patient is receiving a drug known to cause agranulocytosis it is not feasible to do leukocyte counts at frequent intervals as a prophylactic measure Even if this were done it would not always give warning that the disease was impending for the condition manifests itself first in the bone marrow—the changes in the white blood-cell count occur later Furthermore a severe leukopenia may develop within a few hours

the disease only in persons who are sensitive to them

There is a remarkable form called *recurrent or cyclic agranulocytosis* in which the episodes have the identical clinical and hematological aspects of the acute attacks. Such a condition is rare. It occurs at all ages from infancy to old age and appears to predominate in females. It is characterized by recurrent attacks every two or three weeks of fever, chills, and ulcerative lesions in the mouth and throat, with a striking decrease in the total white blood cell count and a reduction or complete disappearance of the neutrophils from the circulating blood. These attacks may occur over a long period; *the longest such period on record is 34 years.* The attacks have been attributed to cyclic infections, to endocrine disturbances, to *deficiency in some factor controlling the development* of the neutrophils in the bone marrow, but none of these explanations has been substantiated. Apparently the attacks are not associated with sensitivity to any type of medication and overactivity of the spleen is not the cause (though improvement may follow splenectomy).

A *chronic* type of *agranulocytosis* has been described in which the manifestations are vague, consisting mainly of chronic fatigue and weakness associated with only a moderate depression of the white blood cell count *and neutrophil percentage. Such a condition* however is rare and the clinical picture is ill defined.

*Primary splenic neutropenia* is a condition in which the total white blood cell count and neutrophil percentage may be greatly reduced over a long term of years (Wiseman and Doan 1939). It should not be confused with agranulocytosis, for primary splenic neutropenia is probably due to hypersplenism, which *results, in some cases in a* selective destructive action on the neutrophils of the circulating blood with a resultant granulocytopenia. In such cases there are (1) splenomegaly, (2) neutropenia, (3) unimpaired production of neutrophils in the bone marrow, and (4) demonstration of splenic overactivity by the epinephrine test. Splenectomy usually affords relief.

*Symptoms and Signs.*—The clinical picture of acute agranulocytosis is *that of a combination of sepsis,* of varying intensity but often severe, with ulcerative lesions of the mucous membranes, usually of the mouth *and throat but sometimes of the vagina* and rectum or other areas. The onset may be abrupt, with fever, chills, sore throat and extreme prostration. Delirium may appear early. The ulcerative lesions may also occur throughout the entire alimentary tract, from esophagus to anal canal. Such lesions are not infrequently in the vagina and on the vulva; in a few instances they have been found on the conjunctivae. Often the condition is a fulminating one, but occasionally there may be only slight soreness of the throat with a mild febrile reaction. Necrosis of the skin is a rare complication, as is jaundice. The latter is due to hepatitis and gives an unfavorable prognosis.

*The liver and spleen are not enlarged* and there is no generalized adenopathy, but the lymph glands draining the ulcerative lesions in the mouth and throat are usually enlarged and tender. In about half the fatal cases there is evidence of a bronchopneumonia. This is a common cause of death, especially among the older patients.

*Blood.*—The striking feature is a pronounced leukopenia which may progress to such an extent that the polymorphonuclear neutrophil cells completely disappear from the peripheral blood. The reduction at first *is only in the granulocytes* but later the lymphocytes and monocytes are also diminished. The total leukocyte count may be reduced to a few hundred cells per cubic millimeter. There is no alteration in the red blood cells unless a preexisting anemia is present or the illness is long continued, and then a slight to moderately severe anemia with a low color index may develop. The platelets are usually normal or increased *except when the illness is prolonged* and they may then become diminished.

*Sternal Aspiration.*—The bone marrow shows either *myeloblastic hyperplasia* with arrest of maturation at the promyelocytic-myelocytic stage but with normal erythropoiesis and thrombopoiesis, or *aplasia of the granulocytic system* with little involvement of the precursors of the erythrocytes or platelets. In the latter condition the prognosis is poor.

in the marrow and in the blood in leukemic cases is the blast form with the single exception that in some of the acute leukemic lymphocytic leukemias it is a cell indistinguishable morphologically from the lymphocyte or prolymphocyte Except in the lymphocytic type cells more differentiated than the pro-stage of the involved series are rare or absent

*Subacute leukemias* are defined as leukemias in which the expected duration of life is from three months to one year from the onset of the first symptom The onset is more insidious than in acute cases but all cases develop fever stomatitis and bleeding into the skin from the gums and mucous membranes within three months from the onset of symptoms The predominant cell in the marrow and blood in leukemic cases is the pro-stage of the involved series and an increased number of blast cells is always found Except in the lymphocytic type cells more differentiated than the pro-stage of the involved series are rare or absent

*Chronic leukemias* are defined as leukemias in which the expected duration of life is from one to twenty years or more the average being from three to five years depending on the type from the onset of the first symptom Fever stomatitis and hemorrhages into the skin or from the gums and mucous membranes rarely develop within the first year The most differentiated stage of the involved series is always present in addition to the less differentiated cells In the lymphocytic type only the lymphocyte is usually found and prolymphocytes are rare or absent

Provision is made so that the leukemias can be further subdivided into leukemic subleukemic and aleukemic forms

*Leukemic leukemias* are defined as leukemias in which the leukocyte count in the blood is above 15 000 per cu mm and the type cells are present in the blood in sufficient number to permit the diagnosis of the type of leukemia

*Subleukemic leukemias* are defined as leukemias in which the leukocyte count in the blood is below 15 000 per cu mm It is often much below normal in the 100 to 4000 range yet the typical cells of the particular variety of leukemia are present in the blood in sufficient numbers to suggest the diagnosis

*Aleukemic leukemias* are defined as leukemias in which the leukocyte count in the blood is below 15 000 per cu mm often as low as 100 to 4000 per cu mm but the typical cells either are absent or are so few usually less than one per 1000 cells that it is impossible to make the diagnosis from examination of the blood alone

In all aleukemic and most subleukemic leukemias marrow examination is essential to establish the diagnosis

*Incidence* —Leukemia has been observed in many species of warm blooded animals and occurs in all races of mankind Generally speaking the disease is more common in males than in females but the ratio of males to females affected varies at different age periods and with the type of leukemia present Lymphocytic leukemia for example has a decidedly higher incidence in males at all age periods and this is especially true of the chronic form in older persons In one series of cases studied at the Simpson Memorial Institute 80 per cent of the females with chronic lymphocytic leukemia were less than 60 years old when first observed whereas 60 per cent of the men were over the age of 60 On the other hand chronic granulocytic leukemia the most common form of the disease in middle life occurs almost as frequently in females as in males Acute leukemia and subacute leukemia affect persons in all age groups but occur most frequently in children and young adults in whom chronic leukemia is uncommon Before puberty there is little difference in the sex incidence of acute leukemia

The incidence of leukemia in the general population is difficult to estimate The Metropolitan Life Insurance Company reports that leukemia takes more than 6000 lives annually in the United States many of them children The death rate reported from leukemia is said to have more than doubled in twenty five years and is more than five times that of infantile paralysis about one and a half times that of measles scarlet fever whooping cough and diabetes combined and almost equal to that of appendicitis

From a practical standpoint, it suffices to warn the patient that taking a drug known to cause the condition may cause infection with fever, chills and sore throat. If these symptoms develop the patient should discontinue the medication immediately and have a leukocyte count made. If a leukopenia is present, antibiotic therapy should be begun at once. Such precautions should prevent a death as a result of the disease.

## LEUKEMIA

By FRANK H. BETHELL, M.D.

*Definition.*—Leukemia is a fatal disease of unknown etiology characterized by excessive and disordered proliferation of leukocytes and their precursors and by varied systemic manifestations resulting from disturbed hemopoiesis and from tissue infiltration.

*Classification.*—Leukemia, according to the view held by most students of the disease, constitutes a malignant neoplasm of leukocyte forming tissue. Therefore it is appropriate to include the leukemias with the malignant lymphomas under the general heading of *Neoplasms of the Hemic and Lymphatic Systems.* Further classification is based upon the cell type involved in the disease, the degree of functional differentiation or maturation of the predominant cells in the circulating blood, bone marrow or lymph tissue, the clinical course and the numerical range of the circulating leukocytes.

As is true of hematologic nomenclature generally, a varied and confusing terminology has been applied to the leukemias. Thus to designate chronic leukemia involving the granulocyte cells of the bone marrow such terms as *myelogenous, myeloid, myelocytic, myelosis, myelemia, myelocythemia, granulocytic, neutrophilocytic* and *leukemic myeloblastoma* have been used synonomously. Multiplicity of terms without defined differences of meaning also characterizes the nomenclature of leukemia affecting the cells of the lymphocytic and monocytic tissues.

In order to provide a system of terminology which would have the merits of uniformity, consistency, comprehensiveness and clarity, the Committee for Clarification of the Nomenclature of Cells and Diseases of the Blood and Blood Forming Organs has recommended that leukemias be classified according to the appropriate cell series and further subdivided as acute, subacute, or chronic and as leukemic, subleukemic or aleukemic. The list of recommended terms follows.

LEUKEMIA

Type unclassified*
Lymphocytic**
  Acute
    Leukemic
    Subleukemic
    Aleukemic
  Subacute
    Leukemic
    Subleukemic
    Aleukemic
  Chronic
    Leukemic
    Subleukemic
    Aleukemic
Granulocytic
  Neutrophilic
  Eosinophilic
  Basophilic
Monocytic
Plasmocytic
Megakaryocytic

* Under this heading may be included such designations as undifferentiated blast cell, stem cell or hemocytoblastic leukemia.

** Each type of leukemia can be subdivided as is indicated for the lymphocytic type.

*Acute leukemias* are defined by the Nomenclature Committee as those in which the expected duration of life is three months or less from the onset of the first symptom. The onset is typically with fever, stomatitis and bleeding into the skin, from the gums and mucous membranes. The predominant cell

types of leukemia are conveniently considered under appropriate headings

1) *Pressure manifestations* due to enlarged lymph nodes spleen or liver and occasionally to myeloid tumors

2) *Tissue infiltration* especially of bone marrow skin digestive tract, kidneys lungs heart, central nervous system and skeletal system

3) *Circulatory disturbances* including anemia hemorrhage, thrombosis and infarction

4) '*Toxic and hypermetabolic manifestations* including fever sweating nervousness heat intolerance, and weight loss

5) *Diminished resistance to infection* especially involving skin mucous membranes and respiratory tract

## CHRONIC GRANULOCYTIC LEUKEMIA

### (Myelogenous Myeloid Myelocytic Leukemia)

The onset of chronic granulocytic leukemia is gradual and the diagnosis may be made in the course of examination for an unrelated illness although accidental recognition is more common of chronic lymphocytic leukemia Usually the disease is well advanced when the patient is first seen and the presenting complaints are most often referable either to anemia or enlargement of the spleen They include increasing fatigability weakness shortness of breath on exertion abdominal fullness and discomfort after eating and not infrequently pain occurring in the left upper quadrant sometimes referred to the left shoulder region and attributable to splenic infarction and diaphragmatic involvement Slight irregular fever is common when the disease is moderately well advanced and the temperature almost always rises to high levels in the terminal phase Symptoms due to increased metabolism may be prominent Purpura and a generalized hemorrhagic tendency do not as a rule occur in chronic granulocytic leukemia until the disease is far advanced Isolated hemorrhages may however occur relatively early in the course of the illness and may be due to leukemic vascular infiltration In the late stages bleeding is due chiefly to thrombocytopenia and generalized capillary damage Thrombotic manifestations include priapism a relatively rare development, but one which is extremely painful and may be the patient's presenting complaint

On examination, the patient with early or moderately advanced chronic granulocytic leukemia often appears healthy and well-nourished although he is frequently apprehensive and nervous and there may be evidence of recent weight loss Pallor of the mucous membranes may be apparent although the face is often flushed The advanced stage of the disease is characterized by progressive emaciation extreme pallor and prominence of the abdomen due to the enlarged spleen and liver Skin lesions are not common in chronic granulocytic leukemia but sometimes are a striking feature of the disease, and are of serious prognostic import They may appear as asymptomatic brown or bluish pinhead to walnut sized raised or flattened circumscribed infiltrations in the skin or subcutaneous tissues Occasionally discrete tumors as large as a golf ball project from the surface of the body and tend to become ulcerated with secondary infection and necrosis Tenderness of the sternum often localized to a small area is present in the majority of patients with chronic granulocytic leukemia

Splenic enlargement usually with preservation of the normal contour of the organ is almost always demonstrable even in patients seen during the earliest recognizable period of the disease Splenomegaly tends to increase with progression of the illness but there is no close correlation between spleen size and clinical course or hematologic changes Enlargement of the liver due to leukemia-cell infiltration is common in the more advanced stages of chronic granulocytic leukemia On the other hand peripheral lymph node enlargement usually is present to only slight degree even in far-advanced chronic granulocytic leukemia

Although not common early in the disease a variety of manifestations due to localized tissue infiltration may be present in chronic granulocytic leukemia These include visual disturbances caused by retinal hemorrhages leukemic retinitis throm

Henshaw and Hawkins state that in 1939–40 leukemia accounted for 3 6 per cent of all deaths due to cancer A number of reports indicate that the incidence of leukemia found at necropsy in general hospitals is slightly less than 1 per cent

Highly suggestive although not conclusive evidence indicates that the true incidence of leukemia is increasing, especially the acute forms of the disease in the younger age groups

*Etiologic Considerations* —As has already been indicated leukemia is generally believed to be a malignant neoplasm In the fourth edition of the *Standard Nomenclature of Disease* leukemia is classified as a new growth affecting specialized mesenchymatous tissue A number of contributory or provocative factors have been presumed to influence the development of leukemia These factors include heredity occupation infection, trauma, and chemical and physical agents

There is no evidence that leukemia is an hereditary disease in the sense of gene transmission On the other hand, an increased incidence of leukemia, particularly the lymphocytic variety in certain families is clearly indicated by numerous reports Congenital leukemia, most often the granulocytic form, has been reported as a rare but well authenticated occurrence It is not unusual for women with chronic leukemia to carry pregnancy to term but there is no recorded instance of congenital leukemia when either parent had the disease

With respect to occupation the recognized incidence of leukemia in physicians is 1 7 times that in the adult white male population and the disease has occurred in radiologists eight to ten times more frequently than in nonradiologists

The theory of an infectious cause for leukemia has received wide credence The nature of the leukocyte changes in leukemia may resemble those observed in known infectious conditions with either neutrophilic or lymphocytic reactions The clinical features of the rapidly progressive forms of leukemia—including fever of "septic" type sweating and the appearance of extreme "toxicity" — simulate those of acute severe infection The chronological relationship between a known infection such as one of the acute exanthemata and the clinical onset of acute leukemia has been noted so frequently as to suggest more than coincidence However, claims for a specific bacteriologic causative agent in leukemia have never been substantiated and there is no evidence of transmissibility of leukemia in man Mammalian leukemia may be transmitted in susceptible inbred strains of animals by inoculation of living cells Fowl leukemia may be transferred from an affected to a healthy bird by means of a cell free Berkefeld filtered tissue extract indicating a viral etiology for this form of the disease Although it appears extremely unlikely that mammalian leukemia is caused by specific infective agents the possible provocative role of infection in inducing leukemia in susceptible individuals is a plausible concept

Leukemia becoming manifest after trauma, especially abdominal injuries and fractures, has received considerable attention in the literature and may have medico legal significance There is no convincing evidence that the leukemia in such instances usually of the chronic granulocytic variety, was not present before the injury

Irradiation, as a physical agent responsible for the development of leukemia, has already received attention in connection with the reported higher incidence of the disease among radiologists The incidence of spontaneous leukemia in susceptible strains of mice has been greatly increased by exposing the animals to gamma radiation or *x* rays

Cases have been reported incriminating many chemicals including therapeutic agents and industrial intoxicants as causes of isolated instances of leukemia With the possible exception of benzol the etiologic role of these compounds in human leukemia is extremely dubious On the other hand it has been well established that carcinogenic agents such as benzpyrene and methylcholanthrene may induce leukemia in experimental animals

*Clinical Manifestations of Leukemia in General* —The symptoms and signs of leukemia are extremely varied and there is wide divergence between the features of chronic leukemias and those of the acute forms of the disease Nevertheless the most common clinical manifestations of all

greater numbers of immature granulocytes particularly myeloblasts and progranulocytes, in the circulating blood and by the development of thrombocytopenia Death is usually due to a cerebro vascular accident generalized bleeding or intercurrent infection with emaciation fever and anemia as contributory factors

## CHRONIC LYMPHOCYTIC LEUKEMIA

(LYMPHATIC LYMPHOGENOUS LEUKEMIA)

As mentioned earlier chronic lymphocytic leukemia tends to occur in an older age group and has a greater predilection for the male sex than is the case with chronic granulocytic leukemia The disease is extremely variable in its symptomatology and course and may remain in an asymptomatic and nonprogressive phase for years As in chronic granulocytic leukemia there may be manifestations due to pressure exerted by leukemic tumors anemia hypermetabolism and leukemic-cell tissue infiltration but in the lymphocytic form of the disease tendency to hemorrhage susceptibility to pulmonary infection and a high incidence of cutaneous manifestations are relatively early and prominent feature

On physical examination the distinguishing feature of chronic lymphocytic leukemia is characteristically bilateral symmetrical enlargement of cervical axillary and inguinal lymph nodes All lymphocytic tissues tend to become involved including medi astinal intra abdominal and retroperitoneal nodes and the spleen The peripheral tumors are of a firm rubbery consistency discrete freely movable and nontender Although occasionally they are as large as baseballs they range more commonly from pea to walnut size Rarely no palpable lymphadenopathy is demonstrable Splenomegaly although usually present is seldom of the degree characteristically associated with chronic granulocytic leukemia Sometimes however in advanced stages of the disease it attains enormous size

The cutaneous lesions may be lymphocytic infiltrations leukemic in nature or non specific secondary skin conditions called *leukemids* The latter may be vesicular urticarial, pustular or hemorrhagic and are often pruritic Both herpes simplex and herpes zoster occur frequently in chronic lymphocytic leukemia

*Hematologic Examination* —In the typical case of chronic lymphocytic leukemia diagnosis is readily made by a glance at the stained blood film The great number of lymphocytes exhibiting striking uniformity in size and staining properties serves at once to identify the nature of the disorder The total leukocyte count is exceedingly variable and although the level is usually in excess of 50 000 cells per cu mm when the patient is first seen subleukemic and aleukemic forms of chronic lymphocytic leukemia are not uncommon On the other hand very high counts counts exceeding 1 000 000 per cu mm , are sometimes observed With progression of the disease greater variations in the character of the lymphocytes occur and increasing numbers of prolymphocytes (inter mediate between lymphoblasts and mature lymphocytes) appear in the circulating blood

Anemia tends to develop later in the course of chronic lymphocytic leukemia than in that of the granulocytic form of the disease When present it is almost always associated with thrombocytopenia In advanced but not necessarily the terminal stages when myelopoiesis is almost completely replaced by proliferating lymphocytes there may be virtually no production of erythrocytes granulocytes or thrombocytes Occasionally secondary or symptomatic hemolytic anemia develops relatively early in the course of chronic lymphocytic leukemia Its recognition is of importance since with appropriate therapy which may include splenectomy the hemolysis can usually be corrected

Bone marrow examination aside from its diagnostic value in subleukemic and aleukemic forms of chronic lymphocytic leukemia is of considerable importance in evaluating the extent of normal myeloid replacement by leukemic cells

*Prognosis* —Although the average duration of life after the onset of symptoms is almost the same in both chronic lymphocytic and granulocytic leukemia—namely about $3\frac{1}{2}$ years the range is much wider in the

bosis of the central retinal vein, optic atrophy, or papilledema Deafness, tinnitus and vertigo may result from involvement of the auditory nerve or the labyrinth Cerebral hemorrhage or thrombosis may lead to hemiplegia Infiltration of nervous tissue by leukemic cells or pressure exerted by cellular proliferation may produce neurologic signs Involvement of skeletal structures causes pain, limitation of motion, pathologic fractures and sometimes transverse myelitis Similarly, other systems may be affected giving rise to a wide variety of clinical manifestations

*Hematologic Examination* —The leukemic form of chronic granulocytic leukemia is *much more common than the subleukemic* or aleukemic varieties When a patient first presents himself with symptoms referable to the disease there is almost invariably moderate or severe anemia The leukocyte count is usually between 100,000 and 300 000 per cu mm and occasionally the value exceeds 500 000 Immature granulocytes are always present and neutrophilic myelocytes and metamyelocytes usually account for 20 to 50 per cent of the *circulating white corpuscles* The *remainder* of the leukocytes are predominantly band and segmented neutrophils but there is characteristically an increase in eosinophilic and basophilic elements including immature forms Myeloblasts are almost always present in the blood but until the process is well advanced their number is relatively small and rarely exceeds 5 per cent in the differential count With progression of the disease to its terminal phase the majority of the white corpuscles become atypical myeloblasts and progranulocytes (promyelocytes with nonspecific cytoplasmic granulation)

The anemia is characteristically normocytic and normochromic except when there is an associated iron *deficiency giving rise* to microcytosis and hypochromia Moderate anisocytosis and polychromasia stippling and occasional nucleated erythrocytes are commonly observed on the stained blood films and there is usually a slight increase in reticulocyte numbers These changes may be present very early in the course of the disease when there is little or no anemia As the condition progresses, frequent transfusions may be required in order to maintain hemoglobin levels compatible with life

The thrombocytes in chronic granulocytic leukemia are usually normal or increased in *number until the disease is far advanced* when profound thrombocytopenia may develop In some cases extremely high thrombocyte counts, exceeding 1 000 000 per cu mm are observed, affording evidence of megakaryocytic involvement in the leukemic process Not infrequently, megakaryocyte fragments are observed in the circulating blood and many of the thrombocytes are large and of bizarre shape The increased number of platelets may be a *factor in thrombus formation*

Bone marrow examination is rarely necessary and is not particularly helpful in the diagnosis of chronic granulocytic leukemia The marrow is diffusely hyperplastic, with relative and absolute increase in granulocytic elements and numerous megakaryocytes Except for heightened activity the maturation of the cells does not appear to be grossly disturbed until in the late stages blast cell proliferation with little differentiation, supervenes *In some cases* abnormalities of erythropoiesis may be apparent characterized by numerous atypical rubriblasts (proerythroblasts) and prorubricytes (early normoblasts)

*Prognosis* —Although the course of chronic granulocytic leukemia may be favorably modified by judicious therapy as a rule treatment has little effect on duration of life Survival after onset of symptoms averages slightly more than three years with great individual variation It is probable that the disease is present in the asymptomatic phase for at least a year Few patients live longer than five years after the diagnosis is made although instances are on record of survival for as long as sixteen years

The duration of life is not correlated with age or sex nor in leukemic cases with the total leukocyte count at the time of diagnosis The course is usually more rapid in patients with the subleukemic form of the *disease* Severe *anemia is an unfavorable sign* *Progression is indicated by decreasing* periods of improvement after therapy by

forms with abundant pale-blue staining cytoplasm containing azurophilic granulation and irregularly shaped nuclei often folded, with a fine net like arrangement of chromatin and small indistinct nucleoli Progressive normocytic normochromic anemia and extreme thrombocytopenia develop early in the course of monocytic leukemia

Bone marrow examination is an essential diagnostic procedure in the subleukemic and aleukemic forms of normocytic leukemia and is of great value in the differentiation of the myelomonocytic and histiomonocytic varieties

## ACUTE LEUKEMIAS

Because of the similarities in clinical manifestations exhibited by the various types of acute leukemia and because identification of the cell series involved in the leukemic process may be difficult it is convenient to consider these entities together The subdivision of the rapidly progressive forms of leukemia into acute and subacute groups is objected to by many as arbitrary and without well-defined criteria of differentiation Nevertheless the distinction appears to serve a useful purpose particularly in evaluating the effects of therapeutic measures which have been recently introduced for the treatment of these disorders In the group classified as acute the patient is severely ill virtually from the time of onset of the first symptom In the subacute group the progress of the disease is more insidious and there is more likelihood of its therapeutic modification Nevertheless the clinical and hematologic features are the same except in degree for the two subdivisions

Of a series of 495 cases of leukemia observed at the Simpson Memorial Institute of the University of Michigan between 1927 and 1940 a total of 168 or 33 9 per cent were classified as acute (including subacute) The incidence of the various types of acute leukemia was as follows

| | *Per Cent* |
|---|---|
| Acute granulocytic (including acute myelomonocytic and hemocytoblastic) | 50 0 |
| Acute lymphocytic | 34 5 |
| Acute monocytic (histiomonocytic only) | 15 5 |

Acute lymphocytic leukemia occurs predominantly in children whereas the granulocytic and monocytic forms of the disease are most common in young adults The latter conditions however may affect persons of advanced age

*Symptoms and Signs* —After an initial period of varying length during which there may be vague symptoms of ill health the course is generally rapid and progressive and resembles that of a severe septic process complicated by hemorrhagic manifestations and severe anemia Pain referred to the bones and joints is not uncommon especially in children Rarely temporary remissions may interrupt the progress of the disease and these may follow an acute infection or the administration of blood transfusions

Physical signs except for fever pallor and hemorrhage including purpura and bleeding from the orifices of the body are not so striking in acute as in chronic leukemias Lymph node enlargement and splenomegaly are usually present but of slight or moderate degree Infection of the oropharynx is common Manifestations due to leukemic-cell infiltration of systems other than the hemic and lymphatic may occur but they are rare in acute leukemia Death is usually due to prostration and toxemia unless the course of the illness has been modified by specific therapy Hemorrhage and intercurrent infection are common terminal events

*Hematologic Examination* —At the time of diagnosis the leukocyte count is usually moderately elevated However almost as frequently the value is either within normal limits or definitely leukopenic Counts above 100 000 per cu mm are uncommon although in acute lymphocytic leukemia there may be a terminal increase to very high levels Immature cells are always present in the circulating blood at some time during the course of the disease but their number may fluctuate widely Usually the majority of the cells are in the blast or prostage of development Their appearance may differ greatly from that of the corresponding elements present in normal marrow or lymph tissue Disparity between nuclear and cytoplasmic development great

former It is believed that this variation is attributable in part to the usual inclusion with chronic lymphocytic leukemia of cases of disseminated lymphosarcoma with blood stream invasion Although this condition is properly classified as a variant of lymphocytic leukemia its course is generally more rapid than that of the typical chronic form of the disease In a series of 61 cases diagnosed as lymphosarcoma cell leukemia the average duration of life after the onset of symptoms was 31 months In the same report the length of survival of 33 cases of typical chronic lymphocytic leukemia was found to be 58 months Many patients live longer than ten years after the diagnosis of chronic lymphocytic leukemia, and their number has constantly increased since the advent of effective measures for combatting *intercurrent infection* Formerly *infection* usually pneumonia was the commonest cause of death in patients with chronic lymphocytic leukemia At present hemorrhage and anemia account for the greatest *number of deaths but, in the older* age groups especially there is a strong possibility that the patient will succumb to a condition unrelated to his leukemia

## *MONOCYTIC LEUKEMIA*

Monocytic leukemia although a recognized entity, is less well defined both clinically and hematologically and its incidence is much lower than either granulocytic or lymphocytic leukemia The course of the disease is usually rapid and the clinical features are in general those characteristic of the acute and subacute forms of leukemia The great majority of patients with monocytic leukemia die within six months of the onset of symptoms the average survival period being about three months Rarely the course of the illness is protracted over a period of years and it has been thought that such cases may *evolve from* a form of non malignant reticulo-endotheliosis

Patients with monocytic leukemia are especially prone to develop lesions of the skin and mucous membranes Gingival hyperplasia with infection and hemorrhage is a common occurrence Cutaneous involvement is most likely to occur over the face and trunk and may take the form of diffuse papules or isolated nodules Secondary bacterial invasion is common leading to the formation of indolent pustules furuncles, or carbuncles These lesions usually have a distinctive violaceous coloration and they may break down to form shallow ulcers Infection of the gingivae tends to extend to the oropharynx leading to necrosis and gangrene Much may be accomplished toward the prevention of these distressing manifestations by a rigid program of oral hygiene and by the local and systemic use of antibiotics with wide spectra of activity

Enlargement of lymph nodes and spleen is not usually a conspicuous feature of monocytic leukemia, and may be absent throughout the course of the illness On *the other hand, hepatomegaly is a relatively* common and prominent manifestation Progression of the disease is characterized by irregular fever generalized bleeding and increasingly severe anemia

*Hematologic Examination* —*Based upon* the supposed origin of the leukemic cells two types of monocytic leukemia are recognized One bearing a close relationship to the granulocytic series of the bone marrow has been termed the *Naegeli type* or *myelomonocytic* leukemia and may be considered a variant of the granulocytic form of the disease The other type which appears to arise directly from the reticulo-endothelial or histiocytic tissue has been designated the *Schilling type* or *histiomonocytic* leukemia and is believed by some to constitute the only true monocytic leukemia

The leukocyte count in monocytic leukemia rarely exceeds 100 000 cells per cu mm and is usually below *50 000* Subleukemic forms of the disease are common but as in all varieties of subleukemic and aleukemic leukemia the peripheral blood picture may change during the evolution of the disease and become frankly leukemic Cells of the monocytic series constitute a variable percentage of the circulating leukocytes the usual range being between 50 per cent and 80 per cent All stages of cellular differentiation are usually represented including blast forms promonocytes and mature *monocytes* as well as both large histiocytic

The nitrogen mustards in particular methyl bis (β chloroethyl) amine hydrochloride, have an inhibitory effect on leukemic cell proliferation The usual dosage of this compound is 0 4 mgm per kilogram of body weight given intravenously in four divided doses at daily or two-day intervals A maximum of 24 mgm in a single course of four doses is advised, and courses of therapy ordinarily should not be repeated more often than every six weeks Nitrogen mustard has a limited field of usefulness in the treatment of chronic leukemia and is contraindicated in the acute form of the disease Its therapeutic effect is induced more rapidly but is of shorter duration than that following irradiation Consequently its greatest value is in the relief of pain pressure manifestations and symptoms of hypermetabolism in patients with terminal chronic leukemia A recently introduced therapeutic agent triethylene melamine (T E M ) is said to have the same pharmacologic action as the nitrogen mustards It may be given orally and does not produce the severe nausea and vomiting which usually follows nitrogen mustard administration The recommended dose is 5 mgm daily until a decrease in the leukocyte count is observed Thereafter the drug should be administered cautiously and in amounts not greater than 5 mgm every second day Both nitrogen mustard and triethylene melamine are powerful myeloid depressants and may induce profound granulocytopenia and thrombocytopenia

Urethane (ethyl carbamate) was introduced in 1946 for the treatment of leukemia Its value is limited essentially to the management of relatively early cases of chronic leukemia particularly the granulocytic variety and its chief application is to cases in which irradiation therapy is impractical The usual dosage at the outset of therapy is from 3 to 4 grams daily in the form of enteric-coated tablets or in solution in a syrupy vehicle Maintenance therapy, employing a reduced dosage of from 1 5 to 2 grams daily may be carried out Gastric intolerance may prevent continued use of urethane and patients receiving the drug should be kept under observation for development of severe leukopenia Transiently favorable effects have followed the administration of urethane in some cases of monocytic leukemia

Arsenic usually employed in the form of solution of potassium arsenite (Fowler s solution), is the oldest agent still in use for the treatment of leukemia It is effective in many chronic cases especially before the disease becomes well advanced but it is generally inferior to other available therapeutic measures In order to obtain the desired results it is usually necessary to increase the drug to the limit of tolerance thereby provoking undesirable side effects including gastrointestinal disturbances weight loss and skin eruptions with pruritus and pigmentation

Until the introduction of the folic acid antagonists and more recently adrenocorticotropic hormone (ACTH) and cortisone there were no specific measures available for the treatment of acute leukemia The rationale for the use of the folic acid antagonists is based upon the observations that folic acid is required for normal hemopoiesis and that rapidly proliferating leukemic cells contain more of the vitamin than do normal cells By inducing a deficiency of folic acid the growth of blood cells and especially leukemic cells is inhibited and in some cases, the supression of leukemic-cell growth enables the body to restore temporarily and in varying degrees normal functional cellular differentiation Unfortunately, the margin between the desired effect on leukemic cells and the accompanying suppression of normal hemopoiesis is narrow and furthermore the widespread metabolic function of folic acid is reflected by serious toxic manifestations when folic acid antagonist therapy is employed The antagonists are chemical analogues of folic (pteroylglutamic) acid and the most powerful and most widely used of this group of compounds is aminopterin (4 amino pteroylglutamic acid) Significant clinical improvement at times virtually complete, but temporary hematologic and clinical remission occurs in about 50 per cent of the children with acute leukemia treated with folic acid antagonists The percentage of adult patients who derive appreciable benefit from antagonist therapy is much smaller Toxic manifestations in

variation in cell size, relatively large nuclei and prominent nucleoli are commonly observed features of leukemic cells

Anemia and thrombocytopenia are almost always present at the time of initial examination of a patient with acute leukemia In the more fulminating cases with little or no production of functional myeloid elements, the shorter life span of the platelets as compared to that of the erythrocytes may lead to profound thrombocytopenia before the development of a significant degree of anemia Such cases have been mistakenly diagnosed as acute idiopathic thrombocytopenic purpura

Bone marrow aspiration aids in distinguishing between the several types of acute leukemia and in subleukemic cases, may be essential to the diagnosis

### Treatment of Leukemia

Roentgen irradiation is the most valuable therapeutic agent available for the management of patients with chronic leukemia This form of treatment first employed by Pusey in 1902, has been applied according to a variety of techniques In general, two points of view have governed the use of irradiation therapy According to one, treatment should be reserved until the disease is manifestly active and should then be applied close to the limit of tolerance The second view which is gaining increasing favor, holds that the aim of treatment should be to maintain the patient in as complete clinical and hematologic remission as possible by the administration of therapy as often as necessary, until the terminal phase of the illness Such a program, employing periodic relatively small doses of irradiation, serves to avoid severe postirradiation sickness and depression and enables the patient to lead an essentially normal life throughout the greater part of his illness Achievement of this objective depends upon close cooperation of the internist and radiotherapist and requires frequent careful clinical and hematologic evaluation of the patient s status

Deep $x$ ray therapy may be applied, in a course of small doses to the entire body with the face and genitalia shielded or may be administered more intensively to a series of localized fields, such as peripheral nodes mediastinum, retroperitoneal region and spleen Choice of the method employed should be governed by the situation presented by the individual patient In general, total body irradiation is preferable during the earlier phases of both chronic granulocytic and lymphocytic leukemia in the absence of great enlargement of the spleen or lymph nodes Local irradiation should be employed for the relief of pressure manifestations or pain due to leukemic cell infiltration and for the reduction of greatly enlarged peripheral lymph nodes

X ray therapy is of no value in monocytic leukemia except in the treatment of local lesions, and its use in acute leukemia is likely to be followed by an enhanced activity of the process Less favorable effects are usually obtained in subleukemic and aleukemic granulocytic and lymphocytic leukemia than in the definitely leukemic form of these diseases Irradiation should be given with caution in the presence of severe anemia or thrombocytopenia a rapid decline in the leukocyte count is an indication for the discontinuance of a course of therapy

Radioactive isotopes and in particular, the isotope of phosphorus $P_{32}$ have been employed for the treatment of chronic leukemia in an increasing number of medical centers since the first report of the use of $P_{32}$ for this purpose by Lawrence in 1940 Radioactive phosphorus offers a convenient means of obtaining widespread irradiation of tissue Its advantages, which are more theoretical than proved depend upon its selectively greater deposition in rapidly proliferating cells its emission of high energy beta rays absorbed within a few millimeters of their point of origin, and its radiation half life of 14 3 days which permits prolonged and if desired continuous irradiation In addition the administration of $P_{32}$ is followed by little or no radiation sickness

The indications and limitations for the use of $P_{32}$ are the same as those for total body roentgen irradiation and there is no convincing evidence that the therapeutic results obtained by its administration are superior to those of $x$ ray therapy

tion It is characterized by diffuse myeloma cell infiltration of the bone marrow and local tumor formation in the bone marrow (this resulting in bone destruction and anemia) by myeloma cell invasion of nonskeletal tissues, hyperglobulinemia and by the frequent presence of a peculiar type of protein in the urine (Bence Jones proteinuria) Plasmocytic myeloma is closely related to the leukemias and may in fact be designated as aleukemic subleukemic or leukemic plasmocytic leukemia depending upon the presence of plasmocytes in the circulating blood

No reliable statistics on the true incidence of plasmocytic myeloma are available Formerly considered a rare disease it is now recognized much more frequently due to the wider use of sternal aspiration in the diagnosis of obscure cases of progressive anemia skeletal pain and osseous lesions The onset of symptoms usually occurs after the age of 40 although instances of the disease have been reported in children Males are affected at least twice as frequently as females

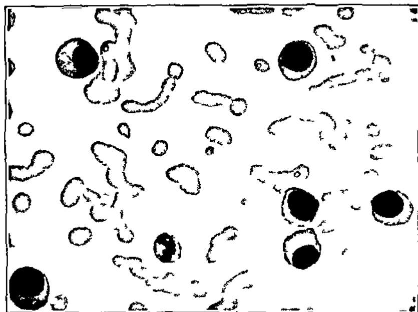

FIG 191 —Photomicrograph showing myeloma cells in material obtained by sternal puncture in a case of multiple myeloma The eccentricity of the nuclei is well shown and the dark ground glass vacuolated cytoplasm is evident (Wintrobe s Clinical Hematology )

Symptoms of anemia weight loss pains in the back or at the site of a pathologic fracture are the most common presenting complaints Physical findings are usually noncontributory, although bone tenderness may be elicited

The liver is often enlarged but the spleen is seldom palpable Roentgenographic examination may reveal the characteristic discrete punched-out osteolytic lesions especially in the skull ribs and pelvic bones Sometimes however the findings are limited to generalized osteoporosis and in some instances the skeletal survey yields negative results

Extra-osseous tissue invasion by myeloma cells is commonly observed at necropsy, but such involvement rarely gives rise to localizing signs Renal insufficiency frequently develops during the course of plasmocytic myeloma and is probably caused by precipitation of abnormal globulins in the tubules Death may be due to kidney failure with uremia

*Laboratory Findings* —Examination of the peripheral blood may reveal no significant abnormalities More commonly there is

addition to granulocytopenia and thrombocytopenia, are referable chiefly to the alimentary tract and include aphthous lesions of the oropharynx and ulceration with hemorrhage of the esophageal gastric, and intestinal mucosa Epilation is a common sequel of antagonist therapy The usual dosage of aminopterin is from 0.5 to 1.0 mgm daily, given either orally or parenterally until an effect is obtained Subsequent administration depends upon individual indications It should be emphasized that folic acid antagonist therapy *is hazardous and its use justified only by the* desperate nature of the illness it is designed to combat

Encouraging early reports of the effects of ACTH and cortisone in cases of acute leukemia have not been substantiated by greater experience in the use of these hormones It is undoubtedly true that the adrenal cortex is concerned with the maintenance of the hemic equilibrium and its stimulation by ACTH or the use of substitution therapy, tends to suppress lymphocytic hyperplasia and promote myeloid cell proliferation and functional differentiation Nevertheless beneficial results of adrenocortical therapy in acute leukemia although sometimes striking are extremely transitory The combined or alternate use of folic acid antagonist and adrenocortical therapy is worthy of consideration in selected cases of acute leukemia

ACTH and cortisone have been advocated for the treatment of chronic lymphocytic leukemia between courses of irradiation Its value in such cases has not been fully determined but it seems to be established that patients with long standing slowly progressive malignant lymphoma may derive benefit from adrenocortical therapy and that the pruritus frequently associated with such disorders may be substantially relieved

## PLASMOCYTIC MYELOMA
### (MULTIPLE MYELOMA)

BY FRANK H BETHEL M D

Plasmocytic myeloma is a neoplastic disease of mesenchymatous tissue exhibiting varying degrees of plasmocytic differentia

tion It is characterized by diffuse myeloma cell infiltration of the bone marrow and local tumor formation in the bone marrow (this resulting in bone destruction and anemia) by myeloma-cell invasion of nonskeletal tissues hyperglobulinemia and by the frequent presence of a peculiar type of protein in the urine (Bence-Jones proteinuria) Plasmocytic myeloma is closely related to the leukemias and may in fact be designated as aleukemic subleukemic or leukemic plasmocytic leukemia depending upon the presence of plasmocytes in the circulating blood

No reliable statistics on the true incidence of plasmocytic myeloma are available Formerly considered a rare disease it is now recognized much more frequently due to the wider use of sternal aspiration in the diagnosis of obscure cases of progressive anemia skeletal pain and osseous lesions The onset of symptoms usually occurs after the age of 40 although instances of the disease have been reported in children Males are affected at least twice as frequently as females

Symptoms of anemia weight loss pains in the back or at the site of a pathologic fracture are the most common presenting complaints Physical findings are usually noncontributory although bone tenderness may be elicited

The liver is often enlarged but the spleen is seldom palpable Roentgenographic examination may reveal the characteristic discrete punched-out osteolytic lesions especially in the skull ribs and pelvic bones Sometimes however the findings are limited to generalized osteoporosis and in some instances the skeletal survey yields negative results

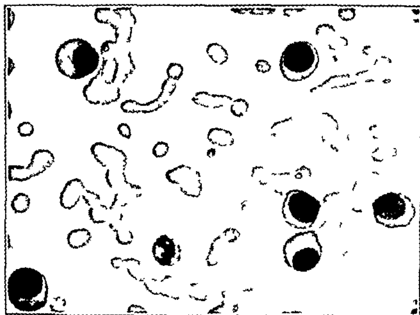

Fig 191 —Photomicrograph showing myeloma cells in material obtained by sternal puncture in a case of multiple myeloma The eccentricity of the nuclei is well shown and the dark ground glass vacuolated cytoplasm is evident (Wintrobe s Clinical Hematology )

Extra-osseous tissue invasion by myeloma cells is commonly observed at necropsy but such involvement rarely gives rise to localizing signs Renal insufficiency frequently develops during the course of plasmocytic myeloma and is probably caused by precipitation of abnormal globulins in the tubules Death may be due to kidney failure with uremia

*Laboratory Findings* —Examination of the peripheral blood may reveal no significant abnormalities More commonly there is

moderate normochromic normocytic or slightly macrocytic anemia. Sometimes the anemia is severe with a hemoglobin value of less than 5 grams per 100 cc. Usually, the leukocyte count is within the normal range or the value is slightly leukopenic, and the differential count is within normal limits. Plasmocytes are not infrequently present. Their detection may require careful search, or they may constitute an appreciable percentage of the total leukocyte number. Very rarely, the picture may be that of true plasmocytic leukemia. Thrombocytes are commonly reduced in number and are usually within the range of from 100 000 to 200 000 per cu mm. Occasionally thrombocytopenia may be of such severity as to cause hemorrhage. A noteworthy feature of the stained blood film is the frequent occurrence of tightly clumped aggregates of erythrocytes. These may appear against a lightly tinted background of dried plasma. Such changes are presumably caused by hyperglobulinemia.

Bence-Jones proteinuria is demonstrable in approximately 65 per cent of the cases of plasmocytic myeloma, although the detection of this abnormal protein in the urine of an individual patient may require repeated examination. Albuminuria and other evidences of renal pathology are frequently observed.

Blood chemical changes commonly but not invariably, occurring in plasmocytic myeloma include the hyperglobulinemia which may exceed 10 grams per 100 cc and an increased level of serum calcium usually within the range of 12 to 16 mgm per 100 cc. As a rule the inorganic serum-phosphorus value is within normal limits. The nonprotein nitrogen and creatinine levels of the serum may be elevated in the presence of renal impairment.

Aspiration of bone marrow from the sternum iliac crest or vertebral spinous process usually serves to establish a cytologic diagnosis in patients with plasmocytic myeloma. Quantitatively, the marrow appearance may vary from almost complete replacement of granulocytic and erythrocytic elements by plasmocytes to the finding of occasional scattered myeloma cells among normally developing myeloid elements. Repeated aspiration is sometimes necessary before conclusive evidence of the disease is secured and rarely biopsy of a localized lesion is required in order to arrive at the diagnosis. Qualitatively, the myeloma cells may have the appearance of extremely primitive forms (plasmoblasts) or may exhibit evidence of increasing degrees of differentiation (proplasmocytes and plasmocytes).

*Prognosis* —Plasmocytic myeloma is usually a slowly progressive disease, death ensuing within two years after the onset of symptoms. Its course may be modified and symptoms relieved by appropriate therapy but therapeutically induced remissions of the type commonly observed in chronic granulocytic and lymphocytic leukemia rarely occur in plasmocytic myeloma. Occasionally however, the disease appears to enter a spontaneous remission and instances of long survival are on record. Death is usually due to cachexia, anemia hemorrhage intercurrent infection (especially pneumonia) or the complications of pathologic fractures, including transverse myelitis.

*Treatment* —Roentgen irradiation to localized regions of involvement may relieve pain especially of radicular origin. Radioactive phosphorus is of limited value but may provide remarkable palliation of symptoms in advanced cases. Stilbamidine has been advocated for this purpose. ACTH or cortisone administration may be followed by considerable subjective improvement and in some cases by increase in erythrocytic values and reduction in plasma globulin. The effect of these hormones however is usually brief. Urethane has been found to be of considerable value in the management of many patients with plasmocytic myeloma. The dosage should be raised to the limit of gastric tolerance usually the dose is 4 0 grams daily given in divided doses with close observation in order to avoid severe toxic marrow depression or hepatic damage.

*Plasmocytic Leukemia* —Occasional plasmocytes are noted in films of the circulating blood in many cases of plasmocytic leukemia. It is unusual for their number to be sufficiently large as to constitute an important

diagnostic aid Rarely however the blood picture may be frankly leukemic Counts in excess of 100 000 per cu mm consisting of more than 90% plasmoblasts proplasmocytes or plasmocytes have been reported When such changes are present the condition may be designated as *plasmocytic leukemia* either acute subacute or chronic depending upon the degree of immaturity of the predominating cells In general the course of the disease is more rapid and the response to therapy less favorable in plasmocytic leukemia than in the more localized myelomas

## INFECTIOUS MONONUCLEOSIS

### GLANDULAR FEVER ACUTE LYMPHADENOSIS

By FRANK H BETHEL M D

*Definition* —Infectious mononucleosis is an acute self limited infection presumably caused by a virus and characterized by fever sore throat and lymphadenopathy It is associated with a distinctive lymphocytic reaction and with the presence of circulating sheep-red-cell agglutinins (heterophil antibodies)

The disorder is a common infection of young persons and is especially prevalent among students Many cases undoubtedly are unrecognized The great majority of cases occur between the ages of 15 and 30 Young children may be affected but the disease is exceedingly rare after the age of 40 Males have the disorder more frequently than females in a ratio of 3 2 Although the disease is undoubtedly infectious with a usual incubation period between 5 and 15 days its order of contagiousness is apparently low Attempts to transmit the infection to human volunteers have met, at best with equivocal success

Typically the onset of infectious mononucleosis is manifested by upper respiratory symptoms and slight fever Headache and malaise are common The throat may be intensely sore The pharyngeal mucosa has a magenta tint rather than the bright erythema of a streptococcal infection Patches of grayish white exudate suggestive of a diphtheritic membrane may be present over the tonsils or pharyngeal lymph tissue Toward the end of the first week of illness sometimes later lymph nodes become enlarged and tender Those in the cervical and axillary regions are most frequently involved Rarely there is no demonstrable lymphadenopathy A transient cutaneous eruption usually macular or maculo-papular may occur during the early period of the illness Ocular manifestations including photophobia and conjunctivitis are not uncommon The spleen is palpable by the end of the second week in more than 50 per cent of cases The organ seldom is greatly enlarged but in rare instances it may be ruptured as the result of relatively slight trauma

Infectious mononucleosis is a generalized disease and there may be foci of mononuclear infiltration in the liver kidneys spleen nervous system and other tissues Such lesions may account for the varied clinical manifestations including the hepatic involvement with or without jaundice and the central nervous system manifestations which may occur during the course of the illness

*Hematologic Examination* —Infectious mononucleosis is a member of a group of diseases which characteristically induce a lymphocytic reaction Such reactions consist of proliferation of lymphocytic elements at varying stages of differentiation including the lymphoid reticulum Hyperplasia of

lymphocytic tissue is accompanied by a reciprocal suppression of granulocytic activity. In the early phase of infectious mononucleosis an interval lasting about a week, there is usually definite neutropenia *with relative lymphocytosis*. *During the* second week, coincident with lymph-node enlargement, the count rises and the characteristic mononuclear cells make their appearance in increasing numbers. These cells are derived from the lymphoid reticulum and vary greatly in their evidences of differentiation, as well as in size and shape. The majority of the mononuclear cells contain nuclei with irregularly massed deeply staining chromatin. The cytoplasm is abundant, has a foamy or vacuolated appearance and shows a tendency to stain more intensely at the periphery of the cell. A variable *number of the mononuclear elements*, usually a small percentage of the total, exhibit the characteristics of lymphoblasts. The nuclear chromatin is diffuse and stains lightly, nucleoli are discernible and the *cytoplasm may be quite scanty* and deeply basophilic. The presence of such cells is likely to suggest the diagnosis of acute lymphocytic leukemia. The leukocyte count may not rise above the normal range throughout the course of the illness but the usual peak is between 12,000 and 20,000 cells per cu mm. Rarely the value may exceed 40,000. Lymphocytes usually constitute between 50 and 80 per cent of the total number of leukocytes.

The erythrocytes and thrombocytes are ordinarily not affected in cases of infectious mononucleosis. However rare instances of associated thrombocytopenic purpura and of hemolytic anemia have been reported. Such complications may be attributed to reticulo-endothelial dysfunction and can probably be regarded as instances of secondary hypersplenism.

The bone marrow is infectious mononucleosis is not *significantly* abnormal and its examination is useful only in differential diagnosis when leukemia is suspected.

The heterophil antibody reaction of Paul and Bunnell which depends upon the agglutination of sheep red cells by antibodies in the patient's serum, has been found to be positive in about 90 per cent of the cases if tested for repeatedly throughout the first three weeks of the illness. A single negative test is of no diagnostic significance. A rising titer is of special diagnostic significance and the specificity of the test may be increased by absorption of the Forssman antibodies. A positive reaction may persist for several months after subsidence of the illness. Non-specific cold hemagglutinins may be present in the serum of patients with infectious mononucleosis and should be prevented from affecting the Paul Bunnell test. False positive serological reactions, for syphilis have been observed in from 10 to 20 per cent of the cases of infectious mononucleosis.

*Prognosis.*—The symptoms of acute illness generally subside within three weeks of the onset of fever in infectious mononucleosis. Lymphadenopathy and splenomegaly may *persist for several weeks or even months*. Return of the blood picture to normal usually coincides with regression of lymph node enlargement. Convalescence may be exceedingly protracted and characterized by ex*treme fatigability and lack of endurance*. Recrudescences of fever and lymphadenopathy occasionally occur. A few fatalities have been reported due to rupture of the spleen or to respiratory paralysis associated with the Guillain Barre syndrome.

*Treatment.*—No therapeutic agents including the more recently introduced antibiotics have been found to influence the course of infectious mononucleosis. They may be of value in controlling secondary bacterial infection particularly in the upper respiratory tract. Restriction of activity during the febrile period of the illness and symptomatic measures should be prescribed.

value it is slowly coming into more frequent use *in this country* At present we believe that it should seldom be used because of *obvious hazards* and as the necessary information can usually be obtained by other means

Splenic enlargement beyond palpability may be due to such infections as typhoid and paratyphoid fevers infectious mononucleosis (up to 1 kg ) acute and subacute obstruction to the circulation may produce enlargement in such conditions as cirrhosis of the liver thrombosis of splenic or portal vein Banti s syndrome congestive heart failure or a movable spleen It is said that *in aortic regurgitation the enlarged organ* may pulsate Even secondary neoplasms may produce a palpable spleen and amyloid infiltration must also be taken into account Of the primary blood diseases

# Chapter 26

# Diseases of the Spleen and the Reticulo-endothelial System

By EDWARD B KRUMBHAAR M D and R PHILIP CUSTER M D

As the spleen is an important member of the reticulo-endothelial system and shares most of its lesions with the other members it is appropriate to consider their diseases together

## THE SPLEEN

THE peculiar anatomy and complex physiology of the spleen make it unusually important for the clinician to be conversant with its peculiar histologic structure, its unique circulatory arrangement * and its capacity as a blood cell reservoir which is second only to that of the liver (Barcroft *et al* ) It is also an important site for the elimination of blood cells apparently acting both as a graveyard and a slaughter house In the leukemias, it contains great numbers of the offending white blood cells (whether by infiltration or local proliferation or both) It appears to have indirect influences on the bone marrow and peripheral blood—peripheral erythrocytes being temporarily fewer in number but more resistant to hemolytic agents after removal of the normal spleen and platelets more numerous whether previously present in normal or decreased numbers The temporary marked increase of neutrophils after splenectomy may be later followed by temporary lymphocytosis and lymph node enlargement There is evidence still inconclusive, of splenic association with endocrine organs and relationships to anti body formation and tumor resistance The spleen is not essential to life in fact, after splenectomy most (or all) of its functions are gradually taken over by other organs

More frequently than any other organ of the body the spleen is found postmortem to be altered by disease in 10 000 autopsies at the Philadelphia General Hospital it was sufficiently changed to appear in the anatomic diagnosis in over 95 per cent In most cases, however the involvement was secondary and often unimportant For various conditions in which the spleen is importantly concerned such as the leukemias Hodgkin s disease polycythemia pernicious anemia the two forms of spherocytic jaundice and Banti s syndrome, the reader is referred to other portions of this book

### DIAGNOSIS OF SPLENOMEGALY

As most disorders of the spleen are accompanied by an enlargement † usually palpable or even extending to the brim of the pelvis the diagnosis of the kind of spleno-

* Fluctuating opinions on the open versus the closed intermediary circulation having veered toward the closed theory after Knisely s studies now lean more toward the open system (A O Whipple) This is important in the pathogenesis of many splenic disorders cp the engorged pulp and relatively empty sinuses of chronic hemolytic jaundice

† Examples weighing up to 8 kilos have been reported whereas Boscus spleen weighing 30 lbs (Lieutaud Historia Anatomico Medica 1767 I p 217) lacks conviction

creasing fibrosis produces a smooth hard rounded spleen cyanotic induration, that should not present difficulties of diagnosis

## Abscess

Abscess is rare, usually hematogenous or the result of a septic infarct or extending from neighboring suppuration The *symptoms* are usually masked by the primary disorder unless a perisplenitis or a rupture with general peritonitis occurs Local pain and tenderness perhaps with a friction rub then accompany the usual signs and symptoms of a severe suppuration One can hardly expect to elicit fluctuation The abscess may rupture into the pleura peritoneum colon or stomach The *prognosis* is grave

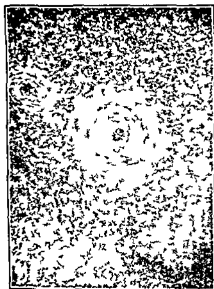

Fig 193 —Section of spleen in Feitis Fleckmilz showing an arteriole with proliferation of the wall especially the intima and a smaller one with hyaline change and beginning fibrosis of pulp (U of Pa Aut 42-17) × 54

*Treatment* —When diagnosed laparotomy is of course indicated As the diagnosis is rarely established before adhesions to neighboring structures have occurred or secondary abscesses formed splenotomy may be safer than splenectomy

## Infarction and Necrosis

Splenic infarction the result of endocarditis septicemia or atheroma of the aorta usually occurs without being recognized clinically If the embolus is sterile the simple anemic infarct is eventually replaced by scar tissue Occasionally a fresh hemorrhagic infarct may be found postmortem The rarer infected embolus causes a septic infarct which like the abscess is largely masked by the parent condition The abscess may be so large that the whole spleen is little more than a sack containing pus The *symptoms* of simple infarct are usually left upper quadrant pain exaggerated by respiration and tenderness Symptoms of septic infarct are like those of abscess The *treatment* is that of the underlying condition

Fig 194 —An almost completely obliterated arteriole surrounded by loose fibrous tissue and showing necrotic material above (U of Pa Aut 42-17) × 30

except for surgical relief of suppuration when present

The peculiar multiple necroses of Feitis (Fleckmilz) due to an obliterating arteriolitis are in themselves of no clinical importance but of considerable interest in relation to similar vascular lesions in the kidney and pancreas

pernicious anemia, the leukemias, hemolytic anemias, early sickle cell anemia and polycythemia all give moderate to extreme enlargement Exophthalmic goiter may be accompanied by enlargement at times considerable Of the primary diseases of the reticulo-endothelial system Gaucher's, Niemann Pick's and Hand Christian's syndromes and neoplasms are considered later in this chapter Banti's syndrome and hemolytic anemia (spherocytosis) are considered under Diseases of the Blood

## Anomalies

The spleen has been found either completely absent usually associated with other anomalies, or double (one of the two being ectopic) Accessory spleens are often found (31 4 per cent in Dorn's 1946 series) These share the fortunes of the larger organ, and therefore should usually be removed when splenectomy is being performed Anomalies of size and shape are of slight clinical importance

## Atrophy

As an organ rich in lymphoid material the spleen may become atrophic with increasing age (to 70 grams or less), though we *have found that it loses but little weight up* to the sixty-fifth year (normal average weight after removal 150 gms though probably much more in the living body) Atrophy occurs early in undernutrition, as in war edema and after experimental removal of the external function of the pancreas and is also found secondary to chronic congestion advanced arteriosclerosis or to local pressure In long standing sickle cell anemia marked fibrosis and atrophy (even less than 10 gms ) have been reported It is normally smaller in negroes than in whites and in women than in men per kilo of body weight

## Movable Spleen (Floating Spleen)

Movable spleens have been found in every part of the abdomen and in the pleural cavity in cases of diaphragmatic hernia *Symptoms* may be absent or part of a complex *of a general* visceroptosis Sometimes they are referred chiefly to some other organ disturbed by the spleen's malposition especially if adhesions have occurred The characteristic splenic notches are useful in *diagnosis*, together with the absence of normal dulness and occasional ability to return the organ to its normal bed

*Treatment*, desirable on general grounds and to forestall torsion, is the same as for general visceroptosis if mechanical supports prove useless splenectomy is indicated

*Torsion* — Torsion a not infrequent complication of movable spleen causes acute abdominal symptoms demanding immediate laparotomy Sudden pain shock enlargement of the spleen and often fever and vomiting are characteristic

*Rupture* —Traumatic rupture may occur in any enlarged diseased spleen or even in normal spleens 'Spontaneous rupture is rare being most often found in chronic malaria also in *infectious mononucleosis, leu*kemia Banti's syndrome torsion abscess infarct It has been reported even in apparently normal spleens Rupture into the peritoneum is often preceded for hours or *days by subcapsular hematoma Symptoms* are those of internal hemorrhage with local pain, abdominal spasm and limitation of left sided breathing They may not appear for some days after the trauma Surgical treatment is imperative and usually requires splenectomy The underlying mechanism is the increased intra abdominal or intrasplenic tension caused by the congestion edema and cellular hyperplasia which also obstructs blood vessels and thus promotes degeneration of the parenchyma and capsule

## Congestion and Acute Splenic Tumor

The acute splenic tumor of *infectious* diseases and intoxications is the commonest lesion of this organ being a combination of active hyperemia with a hyperplasia of both lymphoid and reticulo endothelial elements Found in most acute infections it may reach sufficient size to cause diagnostic difficulties The passive congestion of chronic heart disease or of any condition raising portal venous pressure (congestive splenomegaly) is also a frequent occurrence The pressure in the portal vein may rise to 250 or even 400 mm (water) In the course of time in

problem in management of the case. This primary type (i.e. with minimal tuberculous lesions elsewhere) according to Winternitz may attack either sex at any age (usually twenty to forty years). In the majority the painful somewhat tender enlarged organ was found associated with chronic digestive and respiratory disturbances weakness fever and emaciation. An unexplained tendency to polycythemia has been described. *Splenectomy* has proved a satisfactory form of treatment for these primary types.

*Malaria of the Spleen.*—The huge stone-like spleen of chronic malaria (ague-cake) was for centuries the most important form of splenomegaly until malaria came under the better control of specific treatment in recent times. The tremendous fibrosis often calcified and masses of pigment are characteristic *pathologic* features. The *symptoms* are those common to splenomegaly perhaps with the specific signs of malaria in the blood which should be sufficient for *diagnosis*. These large spleens are prone to rupture.

*Treatment.*—Splenectomy for those cases that do not respond to quinine or other antimalarial drugs must be considered. However it should be approached with greater caution than where elsewhere recommended on account of the numerous and complex adhesions which greatly increase the difficulty of removal. The survivors of this operation are usually greatly improved.

*Siderotic Splenomegaly (Gandi Gamna).* This condition may be mentioned here although the marked fibrosis with iron and calcium deposits has a varied etiology and similar lesions may be found in other organs.

## Cysts

Cysts of the spleen may be *simple* (traumatic embryonal defects dilated lymph spaces breaking down of hematomata and infarcts) *parasitic* (echinococcus) and *neoplastic* (dermoid angioma). If large enough to attract notice a fluctuating mass may be palpable and perhaps tenderness discomfort and a dragging sensation be produced. A quiet lesion may be activated by trauma. *Diagnosis* may be made by tapping though there is a slight danger of spreading a parasite or better by roentgen ray if the wall is sufficiently calcified or by splenectomy.

*Treatment.*—Partial resection is seldom indicated. In the non-parasitic forms, various mechanical supports may suffice. Splenectomy, if required is usually accomplished without difficulty.

## Neoplasms

Primary forms (malignant lymphoma and other types of sarcoma) are uncommon. Secondary tumors are probably not so rare as is usually thought arriving both by extension and by metastasis through blood and lymph channels. The primary site is commonest in the breast then in the skin (malignant melanoma) and next in the pancreas and the stomach. Benign tumors of the spleen are of no clinical importance. *Diagnosis* is usually too late to be of practical value although a few primary tumors have not recurred after removal. The traditional signs of pain and a growing mass in the left abdomen with increasing anemia and emaciation are suggestive when present.

## Hypersplenism

This term introduced by Eppinger (1913) to indicate an increased hemolytic activity of the spleen has come into wider use in recent years as a convenient explanation of the favorable effects of splenectomy in several conditions affecting erythrocytes granulocytes or platelets or all three. However Türk's aphorism (1914) still remains largely true: "The hemolytic diseases are the children and the spleen is their mother but the father is still unknown and possibly there are several fathers." How the spleen does harm other than by the direct action of its macrophages (seen in phagocytosis and in the smaller cell count in the splenic blood than in the arterial) still requires considerable elucidation. There is also at least suggestive evidence that pathological excess of a hormone-like substance manufactured in the spleen inhibits bone-marrow processes of blood-cell manufacture or maturation or both. If granulocytes are selectively in

### Amyloid Infiltration

(Waxy Degeneration, Lardaceous Diseases)

This lesion the spleen being the commonest site of amyloid disease, is most often associated with chronic tuberculosis next with chronic suppurative disease, slow malignant tumors, syphilis and cardiorenal disease in that order It may occur in the so called "primary" form where the "paramyloid" has a slightly different chemical structure The "sago spleen," i e, the follicular type causes little or no general enlargement and is of interest chiefly to the pathologist In one of our cases of primary amyloidosis, however, the markedly enlarged spleen ruptured spontaneously and was responsible for death of the patient In the diffuse form (bacony spleen) the palpable enlargement may be sufficient to cause discomfort (especially when lying on the right side) and possibly pain and tenderness For diagnosis the Congo Red test is useful, especially in secondary types The *prognosis* and *treatment* are those of the underlying condition, except when the great weight requires mechanical support or splenectomy Rarely the infiltration may regress, after removal of the primary cause

### Thrombosis of the Splenic Vein

Thrombosis of the splenic vein, either partial or complete, may produce symptoms lasting for years and distinguishable with difficulty or not at all from Banti s syndrome or other forms of chronic splenomegaly

*Symptoms and Diagnosis* —In acute thrombosis sudden abdominal pain, shock and painful enlargement of the spleen perhaps with gastric hemorrhage are suggestive The addition of ascites indicates portal involvement, and diarrhea with or without blood suggests involvement of the mesenteric vein In the chronic variety the above symptoms in milder and recurrent form together with a tendency to jaundice anemia and leukopenia and a spleen palpable in spite of ascites, give a picture that presents obvious difficulties especially when the symptoms are less pronounced A tendency toward exacerbations may be of diagnostic help If identified, either before or during laparotomy, splenectomy should be performed, and a porto-caval shunt considered if the portal vein is involved

### Cirrhotic Splenomegaly

Often a prominent and early manifestation of portal cirrhosis, this condition must be differentiated from other splenomegalies chiefly by an accurate history, supported by the various liver function tests and needle biopsy of the liver The smooth, firm, congested spleen resembles that of congestive heart failure Treatment should primarily be directed against the diseased liver Splenectomy has in some cases been attended by an improvement, especially in patients with esophageal varices, when it is accompanied by porto-caval shunt

### *Chronic Infectious Splenomegalies*

Space permits consideration here of only three chief varieties further details to be found in other appropriate chapters

*Syphilis of the Spleen* —Syphilis of the spleen a very rare condition nowadays, may occur either in the congenital or acquired forms of the disease in the former case signs being manifested in the first few months of life It appears much more frequently as an enlargement due to diffuse fibrosis (spirochetes rare or absent) than as single or multiple gummata The *diagnosis* depends on the accompanying signs of syphilis, together with an otherwise unexplained palpable spleen and tendency to jaundice and ascites The possibility of the enlargement being due to syphilitic amyloid disease must of course, be considered

*Treatment* —If specific medical treatment fails splenectomy has at times not only produced rapid improvement but permitted the treatment of the general condition to become more efficacious than before

*Tuberculosis of the Spleen* —Tuberculosis of the spleen usually a minor involvement secondary to a more important focus elsewhere and manifested in miliary or conglomerate forms may on rare occasions assume a stellar role In this case the marked enlargement often a single large mass designated as a tuberculoma, may produce a palpable spleen which constitutes the chief

The effects of splenectomy can be partly deduced from the opening statements of this chapter More precise details can be found in recent textbooks of surgery and in Coller s monograph on Indications for and Results of Splenectomy

## THE RETICULO ENDOTHELIAL SYSTEM

Cells of the reticulo-endothelial system are distinguished by their remarkable phagocytic property Their avidity for particulate matter injected into the blood stream of experimental animals led Aschoff and others to regard the aggregate of such cells as a functional unit despite their widespread distribution throughout the various organs and tissues of the body Reticulum cells (fixed histiocytes fixed macrophages) are found in intimate relation with delicate argyrophilic fibrillæ of the tissue framework as well as in the adventitia of small vessels The endothelial elements (to be distinguished from adult vascular lining endothelium) lie along certain blood and lymph sinuses Reticulo-endothelial cells are most abundant in the bone marrow spleen and lymph nodes and include the Kupffer cells of the liver The fixed reticulum and endothelial cells may transform themselves into free ameboid forms (wandering histiocytes wandering macrophages) which may in turn resume a fixed tissue position

The system is capable of progressive hyperplasia sometimes to an extreme degree This feature has partly obscured the experimental results of so called blockade of the system with various colloidal substances because the blockage itself induces such rapid hyperplasia that unblocked cells are ever present in considerable numbers

Continued studies on cells of the reticulo endothelial system have indicated that phagocytosis is but one of their functions that they are probably counterparts of embryonal mesenchymal cells and that they apparently retain the differentiative qualities of mesenchymal cells throughout post natal life particularly as regards hematopoiesis They remain the stem cells of the blood both within the bone marrow and as sources of extramedullary hematopoiesis (myeloid metaplasia)

Under physiologic conditions the cells of this system are concerned with the disposal of effete erythrocytes through phagocytosis The breakdown of the hemoglobin molecule within these cells probably begins with separation of the protein, globin, from the iron-containing fraction hemochromogen Hemochromogen is oxidized to hematin which undergoes further resolution to bilirubin and hemosiderin Bilirubin is excreted by the liver most of the hemosiderin is re used in the synthesis of hemoglobin Worn out leukocytes and thrombocytes are likewise removed by the reticulo-endothelial cells although many leukocytes pass out of the body in the saliva and along mucous membranes especially the gastro-intestinal

The phagocytic function of the reticulo endothelial system is further concerned in maintenance of health by removal of the small numbers of bacteria and inert foreign substances that constantly enter the blood and lymphatic streams Organic foreign matter is digested by intracellular enzymes while inorganic material such as carbon is retained in more or less innocuous desuetude The role of the reticulo endothelial system in the production of antibodies has been challenged by recent studies which indicate that plasmocytes and lymphocytes are more directly concerned However it must be remembered that these two more specialized cell types are direct descendants of reticulo-endothelial elements

### Disorders of the Reticulo-Endothelial System

One may broadly classify disorders of the reticulo-endothelial system as (1) reactive hyperplasias and (2) neoplastic diseases The first group comprises most commonly the chronic granulomatous processes infectious or otherwise in which the response of histiocytes (macrophages) to the noxious agent is outstanding such as in histoplasmosis Boeck s sarcoid silicosis and so on More specifically linked with the reticulo endothelial system are the so called lipodystrophies where the reactive hyperplasia may assume widespread and massive pro

volved, primary splenic neutropenia (Wiseman and Doan, 1942) results if platelet formation is damaged by excessive "thrombocytopen" a lipid formed in the spleen (Moolten *et al*, 1949), thrombocytopenic purpura develops Inhibited formation or excessive destruction of red and white blood cells, and platelets may be caused by panhypersplenism or splenic panhematopenia' (Doan and Wright, 1946) These conditions as in the case of congenital and acquired familial hemolytic anemia, can occur in either primary or secondary forms Differentiation of primary from secondary cases is important as splenectomy is chiefly valuable in the primary forms In fact, it is contraindicated in secondary cases in which a removable cause is found or extramedullary hematopoiesis is compensatory and a more potent factor than the hypersplenism

For the diagnosis of hypersplenism, one expects to find an enlarged spleen (except in most cases of thrombocytopenic purpura) in the peripheral blood a decreased number of erythrocytes granulocytes or platelets, as the case may be a well functioning generally hyperplastic bone marrow (sternal puncture), and an over-active spleen sometimes demonstrated by the epinephrine test This test is done by Doan as follows

> During a fifteen to thirty minute base-line period, under basal metabolic conditions the pulse, blood pressure and two preliminary complete peripheral blood studies are obtained and the splenic outline is traced Depending upon the age and vascular integrity of the patient 0 5 to 1 cc of 1 1000 adrenalin chloride is injected subcutaneously Blood studies are repeated at ten minute intervals until the pulse and blood pressure reach their maximum stimulation which usually coincides with the greatest contraction of the spleen The peripheral blood studies are then continued at fifteen minute intervals until the spleen has relaxed and the biphasic depression of the curve has been obtained
>
> A positive result is indicated by a significant rise in the peripheral blood level of the affected cell type

## SPLENECTOMY

As an intact spleen is not essential to health and can be removed with relative ease unless bound down by adhesions this procedure naturally often comes into consideration In addition to its use in several surgical conditions splenectomy is accepted these days at least as definitely indicated in cases of hereditary spherocytic anemia idiopathic thrombocytopenic purpura, and the hematopenic conditions where ill health persists and no removable cause can be found It has been found valuable in selected cases of a considerably larger group Lahey and Norcross for instance (1948) had good results in the majority of their cases of congestive splenomegaly (especially if taken early) various secondary thrombocytopenic purpuras, idiopathic acquired hemolytic anemia (spherocytosis and fragility of red cells demonstrated in about half the cases) panhematopenia and cysts of the spleen Sustained improvement has sometimes been observed after removal of chronically enlarged spleens in cases of malaria syphilis sickle-cell anemia Gaucher s and even Hodgkin s disease and the leukemias Lahey indeed maintains that splenectomy is indicated whenever the enlargement has lasted for 6 months or more in a well studied case of obscure origin where there is no definite contra indication also that the indication in the individual case rests more with the hematologist than with the surgeon The mortality, which has attained 3 per cent in the best clinics in recent years, should not exceed 5 or 10 per cent Splenectomy is of course contra indicated for metastatic cancer acute leukemia pernicious anemia agnogenic myeloid metaplasia which we regard as a variant of chronic granulocytic leukemia and acute infections and certainly for most other cases of chronic leukemia Hodgkin s disease chronic infections and depressions of hemopoiesis due to removable causes In myeloid metaplasia where the splenic changes are mainly compensating for an incompetent bone marrow splenectomy not only is harmful, but may rapidly cause death

In Felty s syndrome where the splenomegaly has often been found to be due to amyloidosis splenectomy is not indicated nor is the arthritis improved by the operation

Irradiation of the splenic area and ligation of the splenic vein rarely produce some of the effects of splenectomy although both have been advocated in selected cases but without extensive adoption

*Prognosis*.—If the disease becomes manifest in infancy or the central nervous system is involved the outlook is not favorable. The average duration, however, is about 20 years and many patients survive much longer. So-called carriers may never show evidence of the disease.

*Treatment*.—Splenectomy is the only procedure that has proved of value. Transfusions of whole blood before during and after operation lessen the risk materially. The thrombocyte count should be followed carefully after operation and should the level rise well above normal the use of anticoagulant therapy needs be seriously considered. Because the disease is a generalized one, splenectomy cannot be regarded as a cure.

### Niemann-Pick's Disease

This rare disorder occurs in infancy, most cases having been found in Jewish females with no familial tendency evident. It is characterized by extensive accumulation of lipids throughout the reticulo-endothelial system.

*Pathology*.—Virtually all organs are involved and enlarged, more particularly the spleen and, to lesser degree, the liver and lymph nodes. The bone marrow is more or less extensively displaced and the bone cortex thinned. Tissue changes resemble those of Gaucher's disease except that the lipid histiocytosis is more widespread. The characteristic cell is from 20 to 80 microns in diameter and the cytoplasmic vacuoles are spherical. The lipid filling the vacuoles is chiefly a phosphatid (sphingomyelin) which accepts Sudan dyes and Nile-blue sulfate and is soluble in the usual fat solvents. Hemosiderin is not demonstrable in the cells. Lipid deposits have also been noted in ganglion and glial cells.

*Symptoms*.—Gastro-intestinal disturbances usually the first signs of the disease may be found within the first few weeks or months of life. Poor nutrition, retarded development and edema supervene often associated with a brownish pigmentation of the skin. A cherry-red spot in the retina near the macula, typical of amaurotic family idiocy, is sometimes observed. A protuberant abdomen calls attention to the enlarged spleen and liver, and superficial lymph nodes are often prominent. Radiologic studies may demonstrate osteoporosis.

Anemia is not usually severe although hypochromia is sometimes marked owing to general malnutrition and iron deficiency. Neutropenia and relative or absolute lymphocytosis (up to 40 000) and monocytosis are frequently noted. The large lipid bearing histiocytes occasionally enter the circulating blood.

*Diagnosis*.—Differentiation from the infantile form of Gaucher's disease may sometimes prove difficult on clinical grounds alone. Aspiration of the bone marrow or spleen or biopsy of a lymph node will establish the diagnosis conclusively on the basis of cytoplasmic differences already described.

*Prognosis*.—The outlook is bad, the course of the disease being relatively acute. Patients seldom survive the third year of life with death usually resulting from intercurrent infection.

*Treatment*.—Splenectomy has effected temporary improvement in some cases, none in others. Blood transfusions and antibiotic therapy may be employed as indicated to combat infection.

### Hand-Schuller-Christian's Disease

The picture of exophthalmos, diabetes insipidus and yellowish softened areas in the cranium was first mentioned by A. Hand in 1893 but not generally recognized until after Christian's report in 1919 since which time a surprising number of cases have been described in this category. The cause still remains obscure.

The syndrome is manifested chiefly in childhood and somewhat more in males than females, but no racial or familial predisposition has been demonstrated.

*Pathology*.—As in the previous two diseases excessive lipids are found in the cells of the reticulo-endothelial system. Chemical analysis of the tissues shows a high content of cholesterol, cholesterol esters, neutral fat and lecithin. As the disease progresses fibroblastic proliferation becomes more evident and there is an associated eosinophilic

portions, being concerned with the intracellular storage of atypical or over abundant lipids (Gaucher's, Niemann-Pick's Hand-Schuller Christian's diseases xanthomatosis, diabetic lipemia, cholesterolosis), and these are the ones to be considered in this chapter Eosinophilic granuloma of bone, because of its probable relationship to Hand-Schuller-Christian's disease will also be included Letterer-Siwe's disease (nonlipid histiocytosis) is mentioned in this chapter, although its truly neoplastic nature is not yet well established

Neoplasms of the reticulo-endothelial system encompass the malignant lymphomas including Hodgkin's disease, the various leukemias (leukemic and aleukemic) erythremia (polycythemia rubra vera), and myelomatosis These conditions are discussed elsewhere in the book

## Gaucher's Disease

This is an uncommon disease of obscure nature and is transmitted as a Mendelian dominant character the carriers frequently being unrecognized except on biopsy It chiefly afflicts Jewish women It is probably a metabolic disorder concerned with the deposition of complex lipoproteins

*Pathology* —When the disease is well developed, the spleen is generally huge (3 to 4 kilos), firm, and smooth, with pale red exterior, and a granular cut surface with yellow or grayish red irregular spots divided by darker red bands The liver is also enlarged presenting a relatively firm pallid parenchyma Lymph nodes may also be involved In advanced cases bones may be rarefied to a marked degree

The tissues in general but notably the spleen, liver lymph nodes and bone marrow contain nests of so-called Gaucher cells usually in alveolar arrangement sometimes in diffuse sheets The Gaucher cells vary from 20 to 80 microns in diameter and have one or several small eccentrically placed nuclei The bulky cytoplasm is faintly acidophilic, and is only lightly stained by Romanowsky techniques A fibrillar cytoplasmic network can be demonstrated by Mallory's aniline blue-orange G method the characteristic lipid (kerasin a cerebroside or cerebroglycoside) being deposited between the meshes The usual fat solvents will not dissolve kerasin, and it is, at most only faintly stained with Sudan III The cells also contain a few granules of hemosiderin, demonstrable by the Prussian blue reaction

*Symptoms* —The disease usually becomes manifest in early life, occasionally later and pursues a very chronic course Symptoms are generally related to the large spleen which produces discomfort in the left side of the abdomen, sometimes with pain radiating down the left leg The liver and lymph nodes are often palpably enlarged The skin is frequently discolored from a yellow to gray-brown, and wedge shaped pingueculæ of the conjunctiva are not uncommon in adults Indirect illumination may be required to demonstrate the conjunctival lesions Roentgenologic study discloses rarefying bone lesions in most cases and pathological fractures have occurred The central nervous system has occasionally been involved the manifestations of which naturally depend on location of the lesion

Blood studies in some cases show a slight to moderate degree of anemia which is normocytic in type without much evidence of regenerative activity of the marrow Generally, one finds an associated neutropenia and slight decrease in thrombocytes Gaucher cells are rarely encountered in blood smears When the skeleton is widely involved marrow displacement may be so extensive that the anemia leukopenia and thrombocytopenia are very marked In other patients the anemia or panhematocytopenia is apparently due to hypersplenism as evidenced by striking remission after splenectomy

*Diagnosis* —A positive family history chronic marked splenomegaly starting in a young person moderate anemia leukopenia and perhaps thrombocytopenia conjunctival thickening skin pigmentation, and possibly lesions of the bony structure or central nervous system should suggest Gaucher's disease Positive diagnosis rests with the demonstration of the typical cells which may be obtained in virtually all cases by aspiration of the bone marrow Splenic puncture has also been employed in diagnosis Chemical analysis of tissue is confirmatory but not necessary

and plasmocytic reaction and lipid laden histiocytes may be sparse

While the destructive lesions of membranous bones (especially skull pelvic girdle vertebræ) are the most striking any tissue may be affected and biopsy of the bone marrow may show the lipophagic granulomatosis in area not associated with bone rarefaction

*Symptoms*—The insidious onset with underdevelopment (sometimes amounting to actual dwarfism) headaches drowsiness and bone pains is usually manifested in the second or third year The classical syndrome of defects in membranous bones exophthalmos (usually unilateral) and diabetes insipidus is based merely on the fact that in about 85 per cent of cases the bones around the sella turcica and orbit are involved to a major degree with consequent damage to the pituitary and hypothalamus and extension of the granulomatous tissue into the retrobulbar space Deafness and otorrhea result from deposits in the temporal bone while tender gums and loose carious teeth follow involvement of the alveolar processes

Nonregenerative anemia leukopenia and thrombocytopenia of mild-to-moderate degree are sometimes seen and are occasionally marked when marrow displacement is advanced Hypercholesterolemia is commonly found

*Diagnosis*—The symptom complex already mentioned makes the diagnosis easy in the majority of cases Biopsy of an accessible lesion is helpful When older persons are affected the diagnosis may be much more difficult and made possible only by biopsy Though eosinophilic granuloma of bone is regarded as closely allied to Hand Schuller Christian s disease it is important to make the distinction because eosinophilic granuloma is usually responsive to roentgen therapy, whereas typical Hand Schuller Christian s disease is seldom if ever benefited

*Prognosis*—When the disease begins in early childhood the life expectency is seldom more than from 1 to 4 years The outlook is distinctly better in the older age group

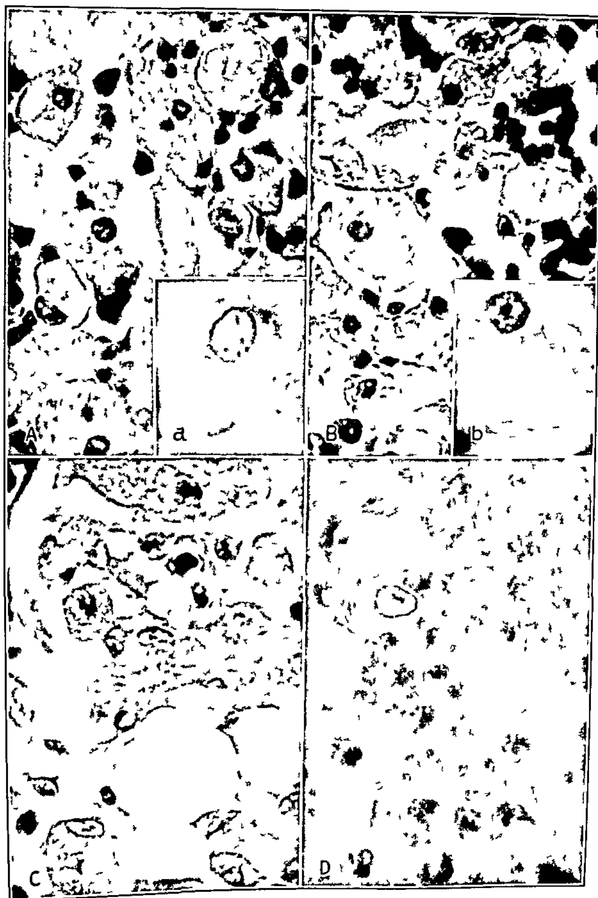
*Treatment*—No specific treatment has been evolved Dietary regulation seems rational especially restriction of fats A trial of roentgen therapy is worth while especially if there is any question of eosinophilic granuloma in the differential diagnosis *

* Without actual figures in support we are of the opinion that of the three diseases just mentioned *Gaucher s disease is the commonest* Hand Schuller Christian s next commonest and Niemann Pick s rarest

---

LEGEND FOR FIGURE 195

FIG 195 —*A Gaucher s Disease* —Reticulo-endothelial cells of the bone marrow richly laden with kerasin displacing the fat and hematopoietic tissue normal to this location Cells of the reticulo-endothelial system elsewhere notably in the spleen show the same changes (H and E stain × 900)



*a* Higher magnification of a Gaucher cell showing the reticulated appearance of the cytoplasm (Mallory s aniline blue- orange G stain × 1890)

*B Niemann Pick s Disease* —Reticulo-endothelial cells of the bone marrow distended with sphingomyelin As in Gaucher s disease this abnormal storage takes place throughout the reticulo-endothelial system (H and E stain × 900)

*b Higher magnification shows the cytoplasm to contain the lipid in both large and fine spherical vacuoles* in contrast to the veining noted in the Gaucher cells (Mallory s aniline blue orange G stain × 1890)

*C Hand-Schuller Christian s Disease* —Section through a defect in a membranous bone discloses an abundance of foam cells the lipid content of which is mainly cholesterol cholesterol esters neutral fat and lecithin (H and E stain × 900)

*D Eosinophilic Granuloma of Bone* —Section through an osteolytic lesion of the tibia presents an abundance of eosinophils readily distinguished by their coarse granularity distributed amongst a background of reticulum cells which have large vesicular nuclei (H and E stain × 1350)

### Eosinophilic Granuloma of Bone

These destructive granulomas of bone may be single or multiple and have been found in all bones except those of the hands and feet, the predilection being for the skull vertebrae, ribs, pelvis, humerus, and femur The lesions have occurred mainly in children and young adults, especially males Tenderness and swelling over the bone generally serve to call attention to them, and roentgenograms show irregular areas of radiolucency These must be differentiated from primary or secondary neoplasms

Tissue curetted from the bone defects is yellowish brown and friable, often with areas of hemorrhage The histologic appearances vary from broad sheets of macrophages, suggestive of tumor at first glance to areas in which admixtures of lymphocytes, plasmocytes, fibroblasts, neutrophils and especially eosinophils signify an inflammatory process Multinucleated giant cells are characteristically found Necrosis and hemorrhage may be extensive As the lesions progress the macrophages engulf fatty substances from the displaced marrow and large foamy cells may predominate simulating the lesion of Hand-Schuller Christian's disease very closely Finally, fibroblastic proliferation may result in spontaneous regression of the lesion and the residual scar may resemble fibrous dysplasia of bone Laboratory studies, apart from showing occasional mild eosinophilia, are not helpful in establishing the diagnosis and microscopic examination of curettings from an affected bone is essential

Healing generally follows curettage of the lesion Equally good results often are obtained by roentgen therapy

### Letterer-Siwe's Disease

This disease is regarded by some authors as another expression of the basic disorder underlying eosinophilic granuloma and Hand-Schuller Christian's disease There is the same focal and diffuse proliferation of histiocytes throughout the tissues, but without the presence of demonstrable lipids within the cells

The disease is characterized clinically by fever, skin rash, progressive hypochromic anemia, and purpura, occasionally with focal destruction of bone It occurs mostly in infants and runs a rapid and inevitably fatal course Whether this disease is inflammatory metabolic or neoplastic still remains a question

### Xanthomatoses and Hypercholesteroloses

A group of clinical syndromes, all associated with orange or yellowish lipid deposits in cells of the reticulo endothelial system mostly in the skin, is included under this heading Recognized varieties are xanthelasma (yellow ovoid papules of the eyelids), juvenile xanthomas of the skin (which tend to be familial), xanthoma tuberosum multiplex (which frequently involve tendon sheaths as well as skin), xanthoma disseminatum (which may affect both skin and mucosa of pharynx and larynx), xanthoma diabeticorum (associated with diabetic lipemia) xanthomatosis generalisata ossium (Shelling and Voshell, 1935), and so-called generalized visceral xanthomatosis

In the early stages of these conditions histologic examination discloses poorly defined nests of lipid laden histiocytes comprising the local lesions There may be an associated inflammatory reaction in the periphery and proliferating fibroblasts not infrequently mask the basic picture The lipid is soluble in the usual fat solvents and shows affinity for fat stains

Hypercholesterolemia is common to this group of conditions, and restriction of fat in the diet is the logical approach to the more widespread or troublesome forms The use of lipotropic substances (choline methionine inositol) may possibly help Xanthoma diabeticorum is generally relieved by adequate treatment of the underlying condition Most of the lesser lesions require no therapy

will, to an extent, vary with individual pain thresholds and with the descriptive terms used. "Heartburn," "gnawing pain," "boring pain," "cramplike pain," "distention," and "gas," for example, may all represent similar underlying processes; the variety is in the degree and the descriptive terms. A burning sensation in the epigastrium or under the sternum—the sensation usually described as heartburn—may be experimentally produced by local balloon distention in the lower esophagus or duodenum. It seems to be essentially motor in character rather than dependent upon chemical changes affecting the mucosa. It is obvious, however, that local ulcerative breaks in the integrity of the mucosa may result in chemical stimulation of the sensory nerves exposed to irritating secretions and therefore also produce a sensation of pain.

It is important to recognize that, as a rule, symptoms arising from the alimentary canal are typically referred to certain segmental areas of the body, a fact of great diagnostic significance in the interpretation of individual histories. Thus disturbances of the upper esophagus are usually productive of symptoms perceived anteriorly under the upper third of the sternum; from the midesophagus under the midsternum; and from the cardiac end of the stomach under the lower third of the sternum or the xiphoid. Gastric disease productive of symptoms usually causes pain referred to the midepigastrium, as does disease in the first portion of the duodenum. In the second and third *portions of the duodenum, sen*sation is usually referred to the midline or somewhat to the right halfway between the xiphoid and the umbilicus. Disease of the jejunum and ileum usually causes discomfort or pain in the periumbilical area, whereas lesions at the ileocecal junction or in the appendix are likely to cause pain at a point halfway between the right anterior superior spine of the ilium and the umbilicus (McBurney's point). Disease of the colon, for the most part, produces hypogastric pain at a level below a line going from one anterior iliac spine to the other. Diseases arising at or near the hepatic or splenic flexures are usually perceived at the point of stimulation or close to it. Sigmoidal pain is most frequently experienced in the left lower quadrant approximately over the course of the sigmoid. Symptoms arising from the rectosigmoid and rectum are usually felt just above the symphysis pubis or in the perineum. It should be pointed out that at any level symptoms may also be felt in the midline of the back at the same segmental level as that of the anterior pain; in some instances only the back pain may occur. If the pain is intense, it may spread laterally from the anterior or posterior points of reference and surround the segment in a zonal distribution. It is obvious that such general localization of pain is subject to variation, and bizarre distributions may be encountered from time to time in individual patients. The presence of major operative scars either in the thorax or in the abdomen frequently causes a deviation of pain reference from the customary site of reference to the scar. Furthermore, lesions involving the general area just above and below the cardiac sphincter are associated with pain almost indistinguishable in distribution from that of angina pectoris, the pain radiating to the shoulder, the arm, and the fingers. The mechanism of pain production by disease of the biliary tract or pancreas probably involves two separate factors. Stretching of the liver capsule or the pancreas secondary to underlying disease may cause steady dull pain, a pain usually referred to a spot over the organ involved. When that organ is the pancreas, back pain at or near the level of the pancreas *and usually somewhat to the left of the spine* is fairly common. If a calculus or some other mechanical block partially obstructs the flow of bile or pancreatic juice, the resulting pain is undoubtedly due to increased tension of the smooth muscle of the duct just above the point of obstruction or of the entire ductal system. Peritoneal irritation due to focal inflammatory disease or metastatic involvement is associated with pain and tenderness over the exact area involved.

The diagnosis of alimentary tract disease must be based on a careful case history, a thorough physical examination, skillful roentgen ray studies, the selective use of appropriate endoscopic procedures, and well chosen laboratory measures. Mistakes in

# Chapter 27

# Diseases of the Alimentary Tract

By CHESTER M JONES MD

*General Considerations of Digestive Tract Disease* —The multiplicity of factors capable of causing digestive symptoms is due to the highly complicated nerve supply of the entire digestive tract the interplay of hormones on the various elements of the tract, and its exposure to numerous irritating or noxious agents For this reason, the successful diagnosis and treatment of digestive diseases must be based on a general understanding of fundamental physiological principles as well as on a knowledge of anatomical details and morphological changes secondary to specific disease processes Unless it is backed by a very sound knowledge of all the facets of internal medicine, gastroenterology indeed becomes too limited a specialty Furthermore a successful approach to the problems of alimentary tract disease must imply the closest collaboration between well trained internists and equally well trained surgeons Because the general nutrition of the body depends in large part upon the normal functioning of the alimentary canal a further comprehension of the principles of dietary adequacy is essential Finally because the entire functioning of all the organs of digestion (in the presence or absence of morbid changes) may be seriously modified by emotional difficulties an awareness of present-day psychiatric practice and thinking is highly necessary

Symptoms arising from the alimentary canal are essentially due to neuromuscular disturbances at one level or another These may be secondary to local or general inflammatory changes local changes in blood supply or alterations in the secretory processes at one level of the tract or another, with resulting changes in digestive and absorptive processes Hypermotility over a small or large segment of the tract, for example may be produced by a specific inflammatory process a new growth or an anatomical abnormality a partially occluding foreign body within the lumen of the tract or occlusion of a localized vascular area supplying the affected portion of the tract with blood Similarly, it may be caused by increased stimulation of the autonomic nervous system Diminished or absent motility with subsequent distention and resulting symptoms may be due to such factors as the administration of narcotics damage to the spinal cord wasting disease with atrophy of the musculature of the intestinal tract and lack of intestinal tone (as in hypokalemia or uremia) or to the distention secondary to the inadequate or delayed carbohydrate digestion and absorption encountered in pancreatic disease the sprue syndrome and the like In any event symptoms arising from the alimentary canal are primarily associated with abnormal smooth muscle function leading to focal or more generalized increase in propulsive activity local spasm or local distention Thus abdominal pain may be produced by the spasm secondary to the administration of morphine or lead to focal ulceration or inflammation or to a more generalized inflammatory process with hypermotility The kind and the degree of the symptoms

as pneumonia typhoid *etc* In the more chronic form of malnutrition the maroon coloration of the tongue is commonly associated with lack of riboflavin or pyridoxin in the diet In pellagra, the tongue is typically red extremely sensitive and atrophy may be more or less a striking feature This appearance may be due in part to nicotinic-acid deficiency, but it is quite probable that other factors are also involved A somewhat different manifestation of a specific dietary deficiency is that encountered in scurvy in which there is a striking swelling of the gums which are not only hyperemic but very spongy and which bleed readily They may become so painful that eating is difficult and loosening of the teeth may occur These manifestations are specifically due to a lack of vitamin C in the diet In pernicious anemia a smooth red, and intensely sore tongue may also be noted but it is not a necessary manifestation of the disease A similar appearance is to be noted in sprue of rather severe grade or of long standing Complete atrophy of the papillae of the tongue, with or without accompanying soreness and superficial ulceration and usually with extreme pallor is encountered in the so-called Plummer-Vinson syndrome and is probably due to iron deficiency as the major contributing factor although there are undoubtedly other nutritional deficits In a given case the degree of papillary atrophy of the tongue or the intensity of the redness may provide a proper measure of the severity of the malnutrition, which may be due solely to dietary inadequacy to specific factors (as in pernicious anemia) or to underlying alimentary tract disease (which may be the cause of anorexia nausea vomiting or diarrhea) Cheilosis may accompany any of these manifestations of deficiency disease Corrective therapy may be limited simply to the provision of specific substances such as riboflavin nicotinic acid and vitamin $B_{12}$ or may merely involve the administration of a general diet that is well balanced and adequate If the changes are secondary to underlying digestive tract disease improvement cannot be satisfactorily achieved until the fundamental process has been sucsessfully attacked

*Infectious Diseases* —The buccal manifestations of infectious disease must include a consideration of such specific infections as measles scarlet fever smallpox, chickenpox syphilis tuberculosis leprosy, and histoplasmosis The Koplik's spots of measles and the strawberry tongue of scarlet fever are usually characteristic and easily recognized The eruption of smallpox and the vesicles of chickenpox regularly appear upon the tongue the palate and the inner surfaces of the cheeks Syphilis, in all its stages may involve changes in the mucous membrane of the mouth These may appear as a chancre of the lip or tongue or as mucous patches on the tongue the lips and the buccal surfaces Condylomata may be seen in the angles of the mouth and, late in the disease gummatous lesions may involve the tongue the lip or the hard palate The diagnosis may be made by dark field examination of material obtained from the lesions or by observation of the associated stigmata of syphilis in other parts of the body Tubercular lesions are most common on the lip the edges of the tongue and the soft palate They are characterized by primary yellowish nodules which gradually ulcerate and enlarge Tubercle bacilli can usually be demonstrated in the discharge from the ulcers Histoplasmosis may cause ulceration of the tongue the lip or the pharynx There is usually involvement of adjacent nodes Diagnosis may be made by discovery of other evidence of the disease or by local biopsy In typhoid fever ulcerations of the mouth are not uncommon They are associated with other manifestations of the disease The lesions of herpes simplex activated by other infectious diseases such as pneumonia epidemic meningitis *etc* may be characterized by vesicle formation and subsequent ulceration the lesions appearing on the lips under the tongue or at the base of the alveolar processes Ulcerative stomatitis may occur in children or in adults and seems to be associated with general dietary deficiency and such local devitalizing factors as dental sepsis It is accompanied by swelling and hyperemia with subsequent necrosis and ulceration along the border of the gums and extension of that necrosis and ulceration to the cheek

diagnosis are more frequently due to an inadequate case history than to any other single cause, a careful and detailed history usually leads to a properly directed and successful search for disease at one level or another *Physical examination, although* of the utmost importance is secondary unless the disease to be diagnosed is so far advanced as to be easily recognized The information obtained by physical examination often merely reflects a general state of nutrition indicative of the degree and duration of disease involvement Routine roentgen-ray studies are often unhelpful because the roentgenologist has not been fully told what the malady suspected is or where it is most likely to be manifested The physician and the roentgenologist should consult each other thoroughly before the *x* ray studies are made

Esophagoscopy, gastroscopy, sigmoidoscopy, and peritoneoscopy necessarily apply to special conditions and require carefully trained physicians Laboratory studies may be classified under two headings specific and general Demonstrating the presence of hyperbilirubinemia, for example or discovering pancreatic enzymes missing from the duodenal juice indicates clearly the site of disease But finding occult blood or undigested food elements in the stools indicates only the presence of an abnormality somewhere in the digestive canal and demonstrating the presence of anemia or hypoprothrombinemia though pointing to various sources for such abnormalities may indicate no more than the severity of some underlying disease Successful treatment obviously demands a demonstration of the specific disease process sought or absolute location of that process as well as a knowledge of the degree of physiological change the numerous factors involved may cause

Proper therapy of alimentary tract disease must include a real knowledge of the normal physiological factors controlling 'digestion," the typical pattern of symptoms associated with individual diseases or syndromes, and the specific measures—medicinal, dietary, and surgical—which may be used to restore or replace function or to remove the cause of focal symptoms The physician must also be fully aware of the dangers and risks associated with various therapeutic measures and the sequelae that may follow such procedures, particularly those related to properly standardized surgical maneuvers which, *nevertheless, may subsequently have a* profound effect upon the patient s nutrition and general health Many types of digestive-tract disease are chronic and are ultimately remediable by proper surgical procedures Physicians should not continue to employ relatively unsatisfactory medical measures when surgery will provide cure or at least reasonable protection against the major symptoms of a given malady A further warning may properly be stressed Many digestive diseases are marked by remissions and exacerbations which may occur spontaneously in the course of the disease rather than because of specific or general medical measures Temporarily excellent results may be erroneously attributed to specific programs or specific medications, these are then unduly prolonged at great expense to the patient but without any adequate therapeutic result In no field of internal medicine is it more important to develop a critical understanding of the life history of given diseases and the mode of action of various therapeutic principles

## DISEASES OF THE ORAL CAVITY

Disease conditions of the oral cavity may be divided into four classes (1) nutritional disturbances (2) specific infectious diseases (3) neoplasms and (4) local changes in the buccal mucosa or the gums changes secondary to specific therapeutic maneuvers noxious agents or constitutional disease

*Nutritional Disturbances* —The effects of malnutrition may frequently be noted in the buccal cavity insofar as these are reflected by atrophy of the papillae of the tongue *with or without local ulceration* along the edges or tip The atrophic process may be so extensive that the tongue is devoid of papillae and presents a totally smooth appearance Extreme redness and slight atrophy may be observed during the immediate postoperative period as a result of starvation and dehydration or it may occur in the course of an acute illness such

as pneumonia, typhoid, *etc* In the more chronic form of malnutrition the maroon coloration of the tongue is commonly associated with lack of riboflavin or pyridoxin in the diet In pellagra, the tongue is typically red, extremely sensitive, and atrophy may be more or less a striking feature This appearance may be due in part to nicotinic-acid deficiency but it is quite probable that other factors are also involved A somewhat different manifestation of a specific dietary deficiency is that encountered in scurvy in which there is a striking swelling of the gums which are not only hyperemic but very spongy and which bleed readily They may become so painful that eating is difficult and loosening of the teeth may occur These manifestations are specifically due to a lack of vitamin C in the diet In pernicious anemia a smooth red, and intensely sore tongue may also be noted, but it is not a necessary manifestation of the disease A similar appearance is to be noted in sprue of rather severe grade or of long standing Complete atrophy of the papillae of the tongue with or without accompanying soreness and superficial ulceration and usually with extreme pallor is encountered in the so-called Plummer Vinson syndrome and is probably due to iron deficiency as the major contributing factor although there are undoubtedly other nutritional deficits In a given case, the degree of papillary atrophy of the tongue or the intensity of the redness may provide a proper measure of the severity of the malnutrition, which may be due solely to dietary inadequacy to specific factors (as in pernicious anemia) or to underlying alimentary tract disease (which may be the cause of anorexia nausea vomiting or diarrhea) Cheilosis may accompany any of these manifestations of deficiency disease Corrective therapy may be limited simply to the provision of specific substances such as riboflavin nicotinic acid and vitamin $B_{12}$ or may merely involve the administration of a general diet that is well balanced and adequate If the changes are secondary to underlying digestive-tract disease improvement cannot be satisfactorily achieved until the fundamental process has been successfully attacked

*Infectious Diseases* —The buccal manifestations of infectious disease must include a consideration of such specific infections as measles, scarlet fever, smallpox, chickenpox syphilis tuberculosis leprosy, and histoplasmosis The Koplik s spots of measles and the strawberry tongue of scarlet fever are usually characteristic and easily recognized The eruption of smallpox and the vesicles of chickenpox regularly appear upon the tongue, the palate, and the inner surfaces of the cheeks Syphilis in all its stages may involve changes in the mucous membrane of the mouth These may appear as a chancre of the lip or tongue or as mucous patches on the tongue the lips and the buccal surfaces Condylomata may be seen in the angles of the mouth, and late in the disease, gummatous lesions may involve the tongue the lip or the hard palate The diagnosis may be made by dark field examination of material obtained from the lesions or by observation of the associated stigmata of syphilis in other parts of the body Tubercular lesions are most common on the lip the edges of the tongue and the soft palate They are characterized by primary yellowish nodules which gradually ulcerate and enlarge Tubercle bacilli can usually be demonstrated in the discharge from the ulcers Histoplasmosis may cause ulceration of the tongue the lip or the pharynx There is usually involvement of adjacent nodes Diagnosis may be made by discovery of other evidence of the disease or by local biopsy In typhoid fever ulcerations of the mouth are not uncommon They are associated with other manifestations of the disease The lesions of herpes simplex activated by other infectious diseases such as pneumonia epidemic meningitis *etc* may be characterized by vesicle formation and subsequent ulceration the lesions appearing on the lips under the tongue or at the base of the alveolar processes Ulcerative stomatitis may occur in children or in adults and seems to be associated with general dietary deficiency and such local devitalizing factors as dental sepsis It is accompanied by swelling and hyperemia with subsequent necrosis and ulceration along the border of the gums and extension of that necrosis and ulceration to the cheek

and lower side of the tongue. It may progress to gangrenous stomatitis or noma. Treatment consists in providing an adequate diet, taking care of carious teeth or necrotic bone, prescribing mouth washes, and administering antibiotics. Gangrenous stomatitis may be fatal unless treated adequately in its early stages. A specific form of ulcerative stomatitis is caused by a mixed *infection due to a fusiform bacillus and a* spirochete. In a typical case the organisms may be easily obtained from a smear of the lesions. In severe cases, this disease, which is known as trench mouth, may be accompanied by fever and constitutional symptoms. An initial hyperemia of the gums is followed by the formation of a dirty membrane and the appearance of patches on the tongue, the cheeks, the palate, and the tonsils. Penicillin therapy is highly effective. Ludwig's angina is due to an acute streptococcal infection involving the floor of the mouth. There are marked constitutional symptoms. Local swelling is striking and the disease is frequently fatal unless energetic treatment is carried out. Therapeutic measures must be prompt and include surgical incision and drainage—tracheotomy if necessary—and the prompt use of chemotherapeutic or antibiotic agents. Diphtherial infection is rarely found about the mouth and tongue. The diphtheritic membrane may extend from the throat to the pharynx and palate and may be an important cause of local symptoms. Specific treatment by the use of a concentrated preparation of the diphtheria antitoxin is obviously the therapy of choice. It should be pointed out that spontaneous bleeding from the gums or the buccal mucous membrane may be a striking manifestation of other diseases, such as thrombocytopenia, due to any cause, the leukemias, or to the hypoprothrombinemia associated with liver disease or chronic diarrheas.

*Neoplasms.*—Cancer of the oral cavity is the cause of approximately 5 per cent of all cancer deaths. It is most common in males. It is usually encountered in the later decades. Involvement of the lip is the most common but carcinomatous disease of the tongue and cheek is not rare. The diagnosis should be suspected if there are the local manifestations of leukoplakia, an indolent ulcer, a papillomatous or nodular tumor, or evident infiltration around a fissure. Successful treatment depends upon early diagnosis and a determination of the type or location of the tumor. If the disease is suspected, biopsy material should be obtained, preferably with the use of electrocautery. Radiotherapy or radical surgery is the only measure to be employed. Other tumors about the mouth include epulis, a fibrous tumor of the gum, ranula, a cyst due to obstruction of the ducts of the mucous or salivary glands under the tongue, and torus palatinus, an exostosis of the palatal processes of the maxilla presenting as a mass in the roof of the mouth. Surgical removal should be carried out in each instance.

*Buccal Changes Due to Noxious Substances.*—Discoloration of the gums may be associated with the toxic effects of bismuth or lead. The bismuth line is located at the gum margin as a series of fine punctate dots of a bluish black color. It is less sharply defined than that associated with lead poisoning. In the case of bismuth, punctate or diffuse pigmentation may occur on the cheeks or the soft palate; occasionally stomatitis or gingivitis, with severe ulceration, may be encountered. Mercury poisoning as a result of therapy or of occupational hazards may result in swollen, tender gums which bleed easily. The local lesions may progress to actual ulceration, with loosening of the teeth and necrosis of the jaw. Dilantin (sodium phenylhydantoinate) may cause soreness and bleeding of the gums, later followed by marked hypertrophy until the teeth are nearly covered. Such an extreme degree of hypertrophy may cause difficulty in chewing and limitation of various dietary factors. Withdrawal of the toxic substance usually results in complete clearing of the local toxic manifestations. Occasionally local surgical measures, or even the treatment of secondary infection, may be necessary. Pigmentation of the gums and cheeks may be associated with other substances, such as silver or arsenic, and may be characteristically observed as a result of adrenalin insufficiency, as seen in Addison's disease.

## DISEASES OF THE ESOPHAGUS

Disease of the esophagus can usually be diagnosed on the basis of a careful history Furthermore because of the fairly accurate localization of pain or discomfort from different levels of the esophagus the site of pathological change or disturbance can frequently be determined with reasonable accuracy The exact nature and location of esophageal disease can only be clarified by careful roentgenologic examination and by esophagoscopy with suitable study of biopsy material

Substernal discomfort or pain as already noted is characteristic of esophageal disease It may go into the back or may spread into one or both arms simulating angina or it may radiate into the neck and postauricular area There is practically always a close relationship between the ingestion of food and the appearance of symptoms The nature of esophageal symptoms varies greatly Intense substernal burning (heartburn) is usually associated with abnormal esophageal function with regurgitation of gastric contents into the lower end of the esophagus or with local smooth muscle spasm at or near the cardia Severe cramping pain may occur in the absence of structural disease but as a rule intense local spasm is associated with developmental abnormalities which act as trigger points for the stimulation of increased motor activity It may also be associated with actual ulceration of the esophagus which ordinarily is to be found in the neighborhood of the cardia Another type of symptom is that of difficulty in swallowing or a feeling of constriction at a certain point beyond which ingested material passes with difficulty Such a symptom suggests obstruction and may be associated with the regurgitation of undigested food In the presence of an esophageal pouch or diverticulum of any magnitude food stasis may occur with putrefaction which results in a foul odor to the breath and the periodic regurgitation of putrid material In the presence of a gradually stenosing lesion a patient almost invariably complains of inability to pass food beyond a certain point This difficulty is first noted in relation to the ingestion of solid foods and eventually may even preclude the successful swallowing of liquid material except in very small quantities Any striking degree of dilatation of the esophagus always implies prolonged duration of the underlying condition With extreme dilatation, there is relatively little likelihood that pain will be a presenting symptom because of the stretching or atony of the esophageal musculature Symptoms associated with obstruction and marked dilatation are therefore characterized by substernal fullness without pain and difficulty in the passage of food beyond a certain point It is obvious that esophageal symptoms of long duration will almost invariably be accompanied by malnutrition of a major degree because of the difficulty in ingesting an adequate amount of food

Physical examinations in patients suffering from esophageal disease may provide evidence of cervical or mediastinal pressure tracheal displacement, metastatic cervical nodes neurological abnormalities and signs of malnutrition It rarely provides direct evidence of esophageal disease

Abnormalities of the esophagus may be classified as follows

1 Motor Disturbances
2 Developmental Abnormalities
3 Neighborhood Disease (Extraluminal)
4 Inflammatory or Traumatic Disease (Intraluminal)
5 Degenerative Disease
6 Neoplastic Disease
7 Esophageal Varices

*Disturbances of Motility* —The most common manifestation of a motor disturbance is heartburn It is frequently encountered in the early months of pregnancy and in hyperreactive individuals The symptom is apt to follow the too-rapid ingestion of food the taking of food when tense or fatigued or the excessive use of tobacco In the absence of structural disease it is usually relieved by regulation of habits or by the use of antacids or antispasmodics Intractable heartburn should suggest the possibility of definite organic disease either in the esophagus or in the stomach duodenum or gallbladder

and lower side of the tongue It may progress to gangrenous stomatitis or noma Treatment consists in providing an adequate diet, taking care of carious teeth or necrotic bone prescribing mouth washes, and administering antibiotics Gangrenous stomatitis may be fatal unless treated adequately in its early stages A specific form of ulcerative stomatitis is caused by a mixed infection due to a fusiform bacillus and a spirochete In a typical case the organisms may be easily obtained from a smear of the lesions In severe cases this disease which is known as trench mouth, may be accompanied by fever and constitutional symptoms An initial hyperemia of the gums is followed by the formation of a dirty membrane and the appearance of patches on the tongue, the cheeks, the palate and the tonsils Penicillin therapy is highly effective Ludwig s angina is due to an acute streptococcal infection involving the floor of the mouth There are marked constitutional symptoms Local swelling is striking and the disease is frequently fatal unless energetic treatment is carried out Therapeutic measures must be prompt and include surgical incison and drainage—tracheotomy if necessary—and the prompt use of chemotherapeutic or antibiotic agents Diphtherial infection is rarely found about the mouth and tongue The diphtheritic membrane may extend from the throat to the pharynx and palate and may be an important cause of local symptoms Specific treatment by the use of a concentrated preparation of the diphtheria antitoxin is obviously the therapy of choice It should be pointed out that spontaneous bleeding from the gums or the buccal mucous membrane may be a striking manifestation of other diseases, such as thrombocytopenia due to any cause the leukemias or to the hypoprothrombinemia associated with liver disease or chronic diarrheas

*Neoplasms* —Cancer of the oral cavity is the cause of approximately 5 per cent of all cancer deaths It is most common in males It is usually encountered in the later decades Involvement of the lip is the most common but carcinomatous disease of the tongue and cheek is not rare The diagnosis should be suspected if there are the local manifestations of leukoplakia an indolent ulcer a papillomatous or nodular tumor, or evident infiltration around a fissure Successful treatment depends upon early diagnosis and a determination of the type or location of the tumor If the disease is suspected, biopsy material should be obtained preferably with the use of electrocautery Radiotherapy or radical surgery is the only measure to be employed Other tumors about the mouth include epulis, a fibrous tumor of the gum ranula, a cyst due to obstruction of the ducts of the mucous or salivary glands under the tongue, and torus palatinus an exostosis of the palatal processes of the maxilla presenting as a mass in the roof of the mouth Surgical removal should be carried out in each instance

*Buccal Changes Due to Noxious Substances* —Discoloration of the gums may be associated with the toxic effects of bismuth or lead The bismuth line is located at the gum margin as a series of fine punctate dots of a bluish black color It is less sharply defined than that associated with lead poisoning In the case of bismuth punctate or diffuse pigmentation may occur on the cheeks or the soft palate occasionally stomatitis or gingivitis, with severe ulceration, may be encountered Mercury poisoning as a result of therapy or of occupational hazards may result in swollen tender gums which bleed easily The local lesions may progress to actual ulceration with loosening of the teeth and necrosis of the jaw Dilantin (sodium phenylhydantoinate) may cause soreness and bleeding of the gums later followed by marked hypertrophy until the teeth are nearly covered Such an extreme degree of hypertrophy may cause difficulty in chewing and limitation of various dietary factors Withdrawal of the toxic substance usually results in complete clearing of the local toxic manifestations Occasionally local surgical measures or even the treatment of secondary infection may be necessary Pigmentation of the gums and cheeks may be associated with other substances such as silver or arsenic, and may be characteristically observed as a result of adrenalin insufficiency as seen in Addison s disease
